The elongation that occurs after yielding before the load starts to increase monotonically is known as the yield point elongation. Yield point elongation leads to nonuniform deformation at low strains in forming operations. If it exceeds approximately 1.5%, irregular surface markings known as Lüders lines or stretcher strains may occur to an extent that is unacceptable in visible parts.

**Tensile Strength.** The maximum stress observed in the test is known as the tensile strength (TS), or ultimate tensile strength (UTS).

Tensile strength determines the maximum load that can be usefully applied in a forming operation.

**Uniform Elongation.** The engineering strain at the maximum engineering stress is known as the uniform elongation,  $e_u$ . Prior to this point, the sample deforms uniformly. Subsequently, deformation concentrates—initially in a fairly large region known as a diffuse neck, and ultimately in a localized region of sharply reduced cross section known as a local neck. Deformation continues to concentrate in this region until fracture occurs.

**Total Elongation.** Elongation at the point of fracture is known as total elongation,  $e_T$ . It has been used extensively as an approximate indication of sheet metal formability. However, no single property is a reliable indicator of formability under all conditions.

**Reduction in area**  $(A_0 - A)/A_0$  is calculated from measurements of actual specimen width and thickness in the narrowest part of the necked region. The true strain, which cannot be determined from length measurements in the post-uniform elongation region, is also calculated from these values.

The true strain in the necked region is equal to  $\ln(dL/dL_0)$ , where  $dL$  is a small element of length in this region, whose original length was  $dL_0$ . Equating the original and final volumes of this element of length gives:

$$V_0 = A_0 dL_0 = V = A dL$$

or

$$\epsilon = \ln\left(\frac{dL}{dL_0}\right) = \ln\left(\frac{A_0}{A}\right) \quad (\text{Eq 9})$$

The relationship between the reduction in area at fracture and the minimum bend radius is described as follows (Ref 25): for values of reduction in area at fracture,  $q$ , below 0.2, the ratio of the minimum bend radius,  $R_m$ , to sheet thickness,  $t$ , is given by:

$$\frac{R_m}{t} = \frac{1}{2q} - 1 \quad (\text{Eq 10})$$

For values of  $q$  greater than 0.2:

$$\frac{R_m}{t} = \frac{(1-q)^2}{(2q-q^2)} \quad (\text{Eq 11})$$

**Strain-Hardening Exponent.** The  $n$  value,  $d \ln \sigma_T / d \ln \epsilon$ , is given by the slope of a graph of the logarithm of the true stress versus the logarithm of the true strain in the region of uniform elongation. For materials that closely follow the Holloman constitutive equation (Eq 4), an approximate  $n$  value can be obtained from two points on the stress-strain curve by the Nelson-Winlock procedure (Ref 26). The two points commonly used are at 10% strain and at the maximum load. The ratio of the loads or stresses at these two points is calculated, and the  $n$  value and uniform elongation can then be determined from a table or graph. The accuracy of the  $n$  value determined in this way is  $\pm 0.02$ .

The  $n$  value can be determined more accurately by linear regression analysis, as in ASTM E 646. For some materials,  $n$  is not constant, and initial (low strain), terminal (high strain), and sometimes intermediate  $n$  values are determined. The initial  $n$  value relates to the low deformation region, in which springback is often a problem. The terminal  $n$  value relates to the high deformation region, in which fracture may occur.

**Plastic Strain Ratio.** The  $r$  value, or anisotropy factor, is defined as the ratio of the true width strain to the true thickness strain in a tension test. Generally, its value depends on the elongation at which it is measured. It is usually measured at 10, 15, or 20% elongation.

The  $r$  value is calculated approximately from the measured width and length as:

$$\epsilon_w = \ln\left(\frac{w}{w_0}\right)$$

$$\epsilon_t = \ln\left(\frac{t}{t_0}\right) = \ln\left(\frac{L_0 w_0}{L w}\right) \quad (\text{Eq 12})$$

**Fig. 10** Methods for determining strain-rate sensitivity ( $m$  value). (a) Duplicate test method. (b) Changing rate method

where constancy of volume ( $Lwt = L_0w_0t_0$ ) has been used and

$$r = \frac{\epsilon_w}{\epsilon_t} = \frac{\ln\left(\frac{w}{w_0}\right)}{\ln\left(\frac{L_0w_0}{Lw}\right)} \quad (\text{Eq 13})$$

The average  $r$  value, or normal, anisotropy ( $r_m$ ), and the planar anisotropy, or  $\Delta r$  value, can be calculated from the values of  $r$  in different directions using Eq 1, 2, 8, and 12.

**Strain Rate Sensitivity.** The  $m$  value,  $d \ln \sigma / d \ln \dot{\epsilon}$ , is determined either from duplicate tension tests performed at different strain rates or from a single test in which the rate is alternated between two levels during the test. These methods are shown schematically in Fig. 10. The  $m$  value can be determined at various strain levels in the region of uniform elongation:

$$m = \frac{\ln\left(\frac{\sigma_1}{\sigma_2}\right)}{\ln\left(\frac{\dot{\epsilon}_1}{\dot{\epsilon}_2}\right)} \quad (\text{Eq 14})$$

In some materials,  $m$  is insensitive to strain (Ref 4, 27). In other materials, however,  $m$  is sensitive to strain and strain rate (Ref 28). In many materials,  $m$  increases and  $n$  decreases with an increase in temperature (Ref 29), sometimes to the extent that superplastic properties develop.

### Determining $n$ and $r$ Values

The time and facilities required for sample preparation and for performing the uniaxial tension test make it difficult to use for online process control. The following simplified tests for determining  $n$  and  $r$  are more suitable for this purpose. The circle arc elongation test and the rapid- $n$  test use tension specimens with two sections that differ in width by approximately 5% to determine  $n$  values. Fracture almost always occurs in the narrow section, but the final measurements are made on the wide section, which elongates uniformly. The  $r$  value can be obtained from these tests, but for ferritic steels, the Modul- $r$  test is faster and easier to perform. This test actually measures the elastic modulus of the specimen and uses an empirically determined correlation between the modulus and the  $r$  value.

**The circle arc elongation test** does not require measurement of the applied loads (Ref 30). It uses a rectangular tension specimen with a reduced width section produced by milling a pair of small circular arc notches on opposite sides. The gage length is marked in the full-width section, and the specimen is pulled to fracture, which usually occurs in the narrow section. The uniform elongation is measured in the full-width section. The value is slightly lower than that obtained in the conventional tension test and gives a slightly lower  $n$  value. However, it is suitable for production control. The  $r$  value can be determined by the additional measurement of the change in width in the full-width section.

**The rapid- $n$  test** provides rapid and fairly accurate measurements of yield and tensile strengths, elongation, and  $n$  and  $r$  values (Ref 31). It requires relatively simple equipment and can be performed in less than 5 min, including specimen preparation. The test is suitable for sheet metals whose properties are represented accurately by the Holloman equation,  $\sigma_T = k\epsilon^n$ . It has been used successfully on low-carbon and stainless steels and on a variety of nonferrous alloys.

The test specimen, which is punched directly from the sheet sample, has the dimensions shown in Fig. 11. Generally, 25 mm (1.0 in.) gage lengths are marked on both the wide and narrow sections, and the specimen is strained to fracture in a manual or motorized load frame or in a tension-testing machine. The yield load is measured if there is discontinuous yielding, and the maximum load is measured. Yield and tensile strengths are calculated from the measured loads and the initial dimensions of the narrow section. If the yielding is continuous, the yield strength can be calculated from the tensile strength and  $n$  value, as indicated subsequently.

An empirically determined correction is applied to compensate for the effect of the sheared edges of the specimens. For steel, this correction reduces the measured yield and tensile strengths by 13.6 MPa/mm (50.0 ksi/in.) of initial sample thickness. The  $n$  value is calculated from:

$$n = \frac{\ln\left(\frac{w_{02}t_0}{w_{f1}t_f}\right) - n}{\left[\frac{\ln(w_{01}t_0/w_{f1}t_f)}{n}\right]} \quad (\text{Eq 15})$$

where  $w_{01}$  and  $w_{02}$  are the initial widths of the wide and narrow sections, respectively;  $w_f$  is the final width of the wide section; and  $t_0$  and  $t_f$  are the initial and final thicknesses of the wide section, respectively. Equation 15 can be solved iteratively in four steps, or by means of a simple computer program, beginning with a trial value of 0.24 for  $n$ .

For materials that do not have a discontinuous yield point, the yield strength can be calculated as:

$$YS = TS \left(\frac{C}{n}\right)^n \quad (\text{Eq 16})$$

where TS is the tensile strength and  $C$  is a constant. For low-carbon steels,  $C \approx 0.02$ . For other materials,  $C$  must be determined empirically. The  $r$  value can be computed from the initial and

final dimensions of the wide section as described previously.

**The Modul- $r$  test** measures the elastic modulus (Young's modulus) of low-carbon steel samples by determining their resonant frequencies by exciting them using an oscillating magnetic field (Ref 32). The elastic modulus is directly proportional to the square of the resonant frequency, and simple empirical relationships exist between the directionally averaged elastic modulus and the  $r_m$  value and between the planar variation of the modulus and the  $\Delta r$  value.

This test uses a flat  $102 \times 6.35$  mm ( $4.0 \times 0.25$  in.) punched specimen and a specially designed, commercially available magnetostrictive oscillator. The specimen is placed inside drive and pickup coils in the oscillator. An alternating current passed through the drive coil produces an alternating magnetic field, which causes magnetostrictive oscillations in the sample. The oscillations induce an alternating current in the pickup coil. This current is used to change the frequency of the current in the drive coil to maximize the amplitude of the oscillations, that is, to obtain the resonant frequency, which is displayed digitally.

The relationships used to determine  $r_m$  and  $\Delta r$  from the resonant frequency,  $f$ , are:

$$E = 4_p L^2 f^2 \quad (\text{Eq 17})$$

$$r = \frac{4822.6}{(E_m - 267.7)^2} - 0.564 \quad (\text{Eq 18})$$

$$\Delta r = 0.031 - 0.0468 \Delta E \quad (\text{Eq 19})$$

where  $E$  is the elastic modulus in gigapascals;  $p$  and  $L$  are the density and length of the specimen, respectively; and  $E_m$  and  $\Delta E$  are defined analogously to  $r_m$  and  $\Delta r$ .

This test provides a more reproducible measure of  $r_m$  and  $\Delta r$  than the conventional tension-testing method and is less sensitive to differences between operators. It can be performed in 5 min, including specimen preparation. When alloy steels or ferritic stainless steels are tested, a different correlation between the modulus and  $r$  value must be used. This must be determined experimentally. When the test is used on coated products, the coating must be removed chemically prior to testing.

### Plane-Strain Tension Testing

In conventional uniaxial tension testing, the sample is strained in the region of drawing; that

Fig. 11 Rapid- $n$  test specimen. Source: Ref 31

is, the minor or width strain is negative. The test does not provide information on the response of sheet materials in the plane-strain state, in which the minor strain is zero. However, it can be modified to produce this strain state in part of the sample. This modification involves the use of a very wide, short sample or the use of knife edges to prevent transverse (width) strain in part of the sample.

**Wide Sample Methods.** Increasing the width of the sample and decreasing the gage length changes the strain state from one with a large negative minor strain component toward the plane-strain state, in which the minor strain component is zero. In the rectangular sheet tension test, samples with length-to-width ratios of 1 to 1, 1 to 2, and 1 to 4 are used to approach the plane-strain conditions (Ref 33). Gage lengths are constrained further by reinforcements welded onto each side of the sample at both ends, thus making the samples three layers thick except in the gage length.

The minimum minor strain obtained with the 1 to 4 length-to-width ratio is  $-0.05$  times the major strain, which is close to the plane-strain condition of zero minor strain. The in-plane strains are measured by means of grid markings on the samples, and through-thickness deformations can be observed by holographic interferometry.

A similar approach was used in testing many wide specimen designs to determine the effect of edge profile and length-to-width ratio on strain state (Ref 34–36). The specimen geometry that yielded the highest center strain at failure with a large region of plane strain is shown in Fig. 12. The plane-strain region, which is arbitrarily taken as the region where  $|e_2/e_1|$  is less than 0.2, occupies approximately 80% of the specimen width. The outer part of the specimen deforms in a similar manner to a standard tension test specimen.

Special grips were developed that exert a high clamping force at the inner contact lines. This minimizes distortion and slippage in these regions, giving the test well-defined boundary conditions. The results of both aforementioned types of wide specimen tension tests correlated well with stress-strain predictions obtained by finite element modeling using materials properties obtained in the standard tension test (Ref 34, 37).

Fig. 12 Plane-strain tensile test specimen. Source: Ref 36

**Width Constraint Method.** In the width constraint method, a rectangular sample is used that has a central gage section reduced in width by circular notches (Ref 38). The gage section is clamped between two pairs of opposing parallel knife edges (stingers) aligned with the sample axis. The knife edges prevent transverse (width) strain in this region. The sample is pulled to fracture in a tension-testing machine, and the plane-strain limit (necking) and fracture strains are determined from thickness measurements made on the fractured sample. This procedure is described in detail in Ref 38. The use of a spring-loaded clamp around the knife edges makes adjustment of the clamp during testing unnecessary.

### Biaxial Stretch Testing

Two tests that determine the properties of sheet metals in biaxial stretching without involving surface friction effects are the Marciniak biaxial stretching test (Ref 39) and the hydraulic bulge test (Ref 40). The Marciniak test subjects the sample to in-plane biaxial stretching, but does not determine the stresses. In the hydraulic bulge test, the stresses can be determined, but the sample is deformed into a dome, which involves out-of-plane stresses and strains.

**Marciniak Biaxial Stretching Test.** A disk of the test material is stretched over a flat-bottomed punch of cylindrical or elliptical cross section. This creates uniform in-plane biaxial strain in the center of the sample, with a strain ratio that is determined by the ratio of the major and minor diameters of the punch. Most testing has been performed with a cylindrical punch, which produces balanced biaxial stretching.

The center of the punch is hollowed out to eliminate friction in this area, and a spacer is placed between the sample and the punch. The spacer is a disk of material similar to that under test—with the same diameter, but with a hole at the center. The experimental arrangement is shown in Fig. 13. As the disk and spacer are stretched over the punch, the hole in the spacer enlarges, and the central part of the test sample is deformed in uniform in-plane biaxial stretching.

The function of the spacer is to reverse the direction of the surface friction experienced by

Fig. 13 Schematic of Marciniak biaxial stretching test

the sample. In the absence of the spacer, the surface friction opposes the movement of the sample over the punch and reduces the maximum strain level attainable. The spacer deforms more easily than the test sample because of the hole in the center, and it exerts a frictional force on the sample directed outward over the punch radius.

For the material to stretch freely, the punch and die radii must be adequate for the thickness of the material under test. A ratio of spacer hole diameter to punch diameter of 1 to 3 has been used successfully. The strains can be measured by using grid circles, squares, or other suitable markings. The test has the following applications:

- Determination of the limiting strains of materials in uniform in-plane biaxial stretching without surface friction
- Application of a carefully controlled level of uniform in-plane biaxial strain to samples with large areas to be used in other tests—for example, tests to determine the effect of different strain paths on the limiting strain levels
- Detection of defects, such as inclusions, by straining a sample of large area to a uniformly high level; defects will cause early localized fracture, usually parallel to the rolling direction

**Hydraulic Bulge Test.** The periphery of a sheet metal sample is clamped between circular or elliptical die rings, and hydraulic pressure is applied on one side of the sample to deform it into a dome, as shown in Fig. 14. The edge of the sample is prevented from slipping by a lock bead placed in the die rings. This consists of a ridge with small radii on one ring and a matching groove on the other.

With circular die rings, the center of the dome has been found to be nearly spherical (Ref 40). The stress and strain states in this region can be determined from the curvature and extension and the fluid pressure. A biaxial test extensometer has been developed that measures the extension and curvature by means of a spherometer and an extensometer that are in direct contact with the dome (Ref 41).

A system for controlling the strain rate in this test was developed (Ref 42) because significantly different test results have been obtained (Ref 43) under conditions of constant strain rate and constant fluid flow. The system

Fig. 14 Schematic of hydraulic bulge test

uses feedback from the extensometer signal to operate a servovalve, which controls the flow of hydraulic oil to the bulge. This system was used to determine the strain rate sensitivity of aluminum alloys to a much higher strain level than is possible in the tension test.

A computerized system is available that uses electronic vision to measure the principal strains and closed-loop feedback to control the strain rate (Ref 44). This system monitors the relative positions of the centers of three closely spaced white dots painted on a black background at the center of the sample. Initially, the dots form a right-angled isosceles triangle. The principal strains are computed from the change in the spacings of the dots and changes in the angle they subtend. This information is recorded and also used to maintain a constant strain rate by controlling the hydraulic pressure. Strains can be computed only once per second, which limits the maximum controllable strain rate.

A camera is mounted so that it maintains a constant distance from the top of the dome and the dots, except for the effect of the curvature of the dome, which is negligible. The stress state is determined by measuring the curvature of the dome with a contacting spherometer and by measuring the hydraulic pressure with a strain gage pressure transducer.

For thin samples, bending stresses can be neglected, and the radial (meridional) stress,  $\sigma_r$ , is given by:

$$\sigma_r = \frac{pR}{2t} \quad (\text{Eq 20})$$

where  $p$  is the hydraulic pressure,  $R$  is the radius of curvature, and  $t$  is the instantaneous thickness. The thickness is calculated from the measured strains using constancy of volume (Fig. 15). At the top of the dome, the sample is in balanced biaxial stretching, and the circumferential stress,  $\sigma_c$ , is equal to the radial stress.

For convenience, it is customary to express the results of hydraulic bulge tests in terms of the true thickness stress and strain. This is done by theoretically superimposing a hydrostatic compressive stress that does not influence deformation and that has in-plane components equal to the actual radial and circumferential tensile stresses. This converts the stress state to a simple uniaxial thickness compressive stress, as shown in Fig. 16.

The true thickness strain,  $\epsilon_t$ , can be obtained from the radial strain,  $\epsilon_r$ , and circumferential strain,  $\epsilon_c$ , by using the constancy of volume condition:

$$\epsilon_t = -\epsilon_r - \epsilon_c \quad (\text{Eq 21})$$

This enables the results to be represented by a true compressive stress-strain curve in the thickness direction. The hydraulic bulge test has the following applications:

- Intrinsic materials characterization in biaxial stretching, which is a very common strain state in production stampings

- Testing to much higher strain levels than those achievable in tension testing (in some cases, by as much as a factor of ten), particularly for heavily cold-worked materials
- Checking the validity of plasticity theories that attempt to predict the yielding behavior of metals in all stress states from properties measured in uniaxial and plane-strain tension testing

Fig. 15 Constancy of volume nomograph

Fig. 16 Addition of compressive hydrostatic stress to biaxial tensile stress

## Shear Testing

Two tests have been developed to determine the properties of sheet metals subjected to planar shear deformation: the Marciniak in-plane sheet torsion test (Ref 45) and the Miyauchi shear test (Ref 46).

**Marciniak In-Plane Sheet Torsion Test.** A flat 50 mm (1.97 in.) square sample is effectively divided into three zones: an inner circular zone, which is clamped; a ring-shaped middle zone, which surrounds the inner zone and is free to deform; and an outer ring-shaped zone, which is clamped. The inner zone is rotated in its plane relative to the outer zone, which deforms the middle zone in shear. The sample is deformed to fracture, and the angular rotations at two radii in the middle zone are measured by means of calibrated drums that rotate with the sheet. This is shown schematically in Fig. 17.

For materials that follow the power law shear strain-hardening relationship:

$$\tau = C\gamma^n \quad (\text{Eq 22})$$

where  $\tau$  is the shear stress,  $C$  is a constant, and  $\gamma$  is the shear strain; it can be shown that (Ref 45):

$$n = \frac{2 \log \left( \frac{R_a}{R_b} \right)}{\log \left( \frac{\alpha_a}{\alpha_b} \right)} \quad (\text{Eq 23})$$

Fig. 17 Deformed Marciniak in-plane torsion test specimen

(a)

(b)

Fig. 18 Miyauchi shear test specimen. (a) Undeformed. (b) Deformed. Source: Ref 46

where  $\alpha_a$  and  $\alpha_b$  are the angular displacements at radii  $R_a$  and  $R_b$ .

Shear fracture occurs where the shear stress is greatest—at the inner radius,  $R_0$ , of the deforming ring. The shear fracture strain,  $\gamma_f$ , is given by:

$$\gamma_f = \frac{2\alpha_a \left( \frac{R_a}{R_0} \right)^{2/n}}{n} \quad (\text{Eq 24})$$

This test enables the forming properties of sheet metals to be determined at much higher strain levels than is possible in the uniaxial tension test and in a different strain state, that is, in shear.

**The Miyauchi shear test** determines the properties of sheet metals in planar shear deformation by means of a modified tension technique (Ref 46). The test uses flat, rectangular specimens whose ends are divided into three equal sections by parallel longitudinal slits, as shown in Fig. 18(a).

The specimen is clamped in a fixture that prevents out-of-plane deformation. The inner and outer sections are then pulled in opposite directions in a tension machine. This produces a shear stress in the regions between the inner and outer sections and deforms the specimen, as shown in Fig. 18(b). The deformation in these regions is uniform, except at the ends.

The shear strain,  $\gamma$ , is the tangent of angle  $\theta$ , which is the change in direction of lines scribed across the specimen as they pass through the shear zone, as shown in Fig. 18(b). The strain can also be determined from the displacement of the inner section once a relationship has been established between the displacement and  $\theta$ , which must be done for each type of sheet metal tested. Shear stress-strain curves are given in Ref 46 for three different steels. These curves show differences in the strain dependence of the work-hardening coefficient from that in the tension test.

## Hardness Testing

Hardness, or the resistance to indentation by a concentrated load applied by a suitable indenter, has been used in many stamping plants as a measure of formability. Generally, formability decreases with increasing hardness, but the fine-

scale correlation between these properties has not been reliable. The test can be used effectively to monitor changes in a particular grade of material caused by changes in processing that may affect formability.

For steels, hardness measurements correlate well with yield strength values (Ref 47). Therefore, hardness testing is useful in quality control to ensure that the material in use is the specified grade and has the required strength level.

The Rockwell hardness test (ASTM E 18), which is described in detail in the article "Macro-indentation Hardness Testing" in Volume 8 of *ASM Handbook*, is typically used to determine the hardness of such materials. The load and indenter must be selected for the gage and hardness range of the material according to the test specification to ensure that the indentation is the appropriate size. If the indentation is too deep in a sheet sample, the reading will be artificially high because of the influence of the supporting anvil. This becomes a more serious consideration with the use of thinner gage sheet metal in many industries. For thicker and harder materials, the Rockwell B scale is commonly used, and for thinner or softer materials, the Rockwell 30T superficial scale is used. Hardness readings are influenced by the degree of flatness and surface conditions. In addition, the presence of cold-worked surface layers can cause high hardness readings that suggest a lower formability level than actually exists.

## Simulative Tests

For many forming operations, tests that simulate the operation are more useful and relevant than fundamental intrinsic property measurement tests. These tests subject the work material to deformation that closely approximates the production operation, including the effects of factors not present in the intrinsic tests, such as bending and unbending and friction between the work materials and die surfaces. Because these additional factors are present, simulative tests tend to be less reproducible than intrinsic tests and must be performed under carefully controlled conditions to minimize variability in the results. Simulative tests can be classified on the basis of the predominant forming operation involved: bending, stretching, drawing, and stretch-drawing. In addition, tests have been developed to measure wrinkling and the springback that occurs after bending or another forming operation.

## Bending Tests

Two types of bending tests relate to sheet metal forming: simple bending and stretch-bending tests. Simple bending tests are useful in predicting how the sheet metal will perform when bent without tension, as in a hemming operation. Stretch-bending tests relate the

response to combined bending and stretching, as when sheet metal is pulled over a punch or die radius.

**Simple bending tests** can be performed in various ways (ASTM E 290). The simplest method for thin sheet material is to clamp a specimen and a bending die in a vise, as shown in Fig. 19, and to bend the specimen over the die manually or with a nonmetallic mallet.

If the specimen bends through  $180^\circ$  without fracturing or cracking, the experiment is repeated using a bending die of smaller radius. A modified test is performed for highly ductile metals that have extremely small bend radii. The specimen is initially bent at its midpoint, through less than  $90^\circ$ , over a small radius. The test is then completed by pressing the ends of the specimen together between flat platens without a bending die placed between the platens.

The ratio of specimen width to thickness should be greater than 8 to 1, and sheared edges should be machined, filed, or sanded to remove the heavily cold-worked metal present. The orientation of the specimen with respect to the rolling direction may be important because it affects the resistance of the specimen to fracture. Specimens cut perpendicular to the rolling direction usually require a larger bend radius and therefore provide a more conservative measure of this property.

For low-carbon sheet steels, the minimum bend radius is usually not a limiting factor. For high-strength steels and aluminum alloys, it sometimes is, and methods such as rope hemming, which increase the bend radius, have been developed to prevent cracking during the hemming of these materials.

**Stretch-Bending Tests.** A rectangular strip of sheet metal is clamped at its ends in lock beads and deformed in the center by a punch, as shown in Fig. 20. There are two types of stretch-bending tests: the hemispherical test, in which a hemispherical-tipped punch and a concentric circular lock bead are used, and the angular test, in which a wedge-shaped punch and straight parallel lock beads are used. The hemispherical test involves a range of strain states. The angular test produces the plane-strain state.

The punch travel between initial contact and specimen fracture is measured. The conditions

are chosen so that fracture occurs in the region of punch contact. When fracture occurs in the unsupported region, which tends to happen with narrow thin-gage specimens and large punch radii, the test effectively becomes a tension test.

The results of several hemispherical and angular stretch-bending tests on three types of steels and an aluminum alloy have been reported (Ref 48). For the hemispherical test, the effects of variations in punch tip radii ranging from 3.2 to 51 mm (0.13 to 2.0 in.), in sheet thicknesses ranging from 0.5 to 3.3 mm (0.02 to 0.13 in.), and in specimen widths ranging from 25 to 203 mm (1.0 to 8.0 in.) were investigated in the dry and lubricated conditions. The tests showed that the height at fracture increased with increasing punch radius and sheet thickness and with the use of lubricants. It decreased with increasing specimen width in the range of 102 to 203 mm (4.0 to 8.0 in.), in which fracture occurred in the region of punch contact. The ranking of two of the steels was found to be dependent on specimen thickness.

Fewer conditions were investigated in the angular test. The results for a 76 mm (3.0 in.) wide specimen and punch radii ranging from 1.6 to 6.4 mm (0.06 to 0.25 in.) showed much greater heights than for the same conditions in the hemispherical test. Increases in height with increasing punch radius were also evident, but in contrast to the hemispherical case, a decrease with increasing thickness was observed. Correlation between the results of these tests and production experience is reported to be fairly good.

Data from the angular stretch-bending test have been analyzed and indicate that fracture occurs at a constant limit strain that is independent of sheet thickness and punch radius (Ref 49). Stretch-bending tests are useful for materials selection and for predicting the effects of materials substitution and gage reduction in many forming operations.

### Stretching Tests

Historically, ball punch tests, such as the Olsen cup test and Erichsen cup test, have been used to determine the properties of sheet metals in stretching. These tests stretch a specimen over a hardened steel ball and measure the height of the cup produced. Tests that stretch the specimen

over a much larger hemispherical dome have been developed, including the limiting dome height test (LDH), which uses specimens of different widths to control the strain ratio at fracture.

Many forming operations involve stretching an edge of a part or a cutout (hole) in a part. For example, when a concavely contoured edge is flanged, the metal is stretched. The ability of the material to undergo this type of forming operation can be measured by the hole expansion test. In this test, a cylindrical, hemispherical, or conical punch is pushed through a circular hole of smaller diameter in the specimen. This initially increases the diameter of the hole and then forms a rim of stretched metal. The edge ductility of the material is indicated by the amount of hole expansion that occurs without edge cracking.

**Ball Punch Tests.** The Olsen and Erichsen cup tests are similar, differing principally in the dimensions of the tooling used. The Olsen test (ASTM E 643) uses a 22.2 mm (0.875 in.) diameter hardened steel ball and a die with a 25.4 mm (1.0 in.) internal diameter (28.6 mm, or 1.125 in., for gages over 1.5 mm, or 0.06 in.) and a 0.81 mm (0.032 in.) die profile radius, as shown in Fig. 21. The Erichsen test, which is extensively used in Europe, uses a 20 mm (0.79 in.) diameter ball and a die with a 27 mm (1.06 in.) internal diameter and a 0.75 mm (0.03 in.) die profile radius.

In both tests, the cup height at fracture is used as the measure of stretchability. The preferred criterion for determining this point is the maximum load. When this cannot be determined, the onset of a visible neck or fracture can be used, but this yields a slightly different value. The cup height measured by means of a visible fracture is 0.3 to 0.5 mm (0.012 to 0.020 in.) greater than the height measured at the maximum load.

These tests, as indicators of stretchability, should correlate with the  $n$  value, but the correlation is not satisfactory. Improved correlations with the total elongation (Ref 50) and reduction in area (Ref 51) have been reported. Some investigators have reported poor reproducibility of results in the Olsen and Erichsen tests and poor correlation with production experience (Ref 52, 53). Satisfactory reproducibility and correlation in specific cases have been reported when

Fig. 19 Schematic of simple bending test

Fig. 20 Schematic of stretch-bending test

Fig. 21 Schematic of Olsen cup test

experimental conditions were carefully controlled (Ref 50).

The variability in tests has been attributed to the small size of the penetrator, uncontrolled drawing-in of the flange, and inconsistent lubrication (Ref 52, 53). The small size of the penetrator leads to excessive bending, particularly in thicker sheet, and is generally unrepresentative of production conditions. Drawing-in can be controlled somewhat by standardizing the specimen size and by using a high (~71 kN, or ~8 tonf) clamping force. Even greater control can be achieved by using lock beads or serrated dies (dies with concentric circular ridges of triangular cross section that dig into the specimen and prevent slippage).

Consistent lubrication can be achieved by using oiled polyethylene between the specimen and penetrator. The problems with the Olsen and Erichsen tests have led to the development of stretching tests that use a much larger diameter punch and a lock bead to prevent drawing-in.

**Hemispherical dome tests** using 50.8, 76.2, and 101.6 mm (2.0, 3.0, and 4.0 in.) punches have been reported (Ref 52, 53). A 100 mm (3.94 in.) test is the most widely used. Typical tooling designed for this test is shown in Fig. 22. The lock bead, in combination with a hold-down force of about 222 kN (25 tonf), completely prevents drawing-in of the flanges.

The specimens fracture circumferentially at a distance (for lightly lubricated low-carbon steel) of 35 to 40 mm (1.38 to 1.57 in.) from the pole, at which point the radial strain peaks sharply. The circumferential strain varies gradually from a maximum of 10 to 20% at the pole to zero at the lock bead.

The hemispherical dome test yields more reproducible results than the Olsen and Erichsen cup tests. For low-carbon steels, the dome height, which is measured at the point of maximum load, increases linearly with the  $n$  value. For a wide range of material (including brasses, aluminum alloys, and zinc), optimal correlation is found between the dome height and the total elongation, which incorporates the effects of strain rate hardening and limiting strains.

Overall, the use of lubrication in hemispherical dome tests is beneficial. A thin layer of a standard lubricant, applied in a consistent manner, reduces scatter in test results, simulates production conditions more closely, reduces damage to the tooling, and simplifies specimen preparation. The improved sensitivity obtained in the dry condition is negated by the increased scatter in the results.

The use of lubrication makes the strain ratio at fracture more biaxial. This is undesirable for production simulation because most production failures occur in the region of plane strain, that is, in a less biaxial manner. To control the strain ratio at fracture, specimens of different widths were used (Ref 54). This technique has been developed further into the limiting dome height test (Ref 55, 56).

**Limiting Dome Height (LDH) Test.** Specimens of various widths are held in a circular lock

bead and stretched over a 100 mm (3.94 in.) dome using tooling of the type shown in Fig. 22. In principle, this test can be used to duplicate a large range of production failure strain states and to select the most suitable material for each particular operation. In practice, most production failures occur close to plane strain, which is generally the strain state at the minimum on a plot of dome height versus specimen width. Consequently, attention has concentrated on this minimum value.

When testing a new material, initial tests should be performed to determine the specimen width that yields the minimum dome height, or LDH<sub>0</sub> value, and the corresponding minor strain. Once this has been established, tests can be conducted at this width only. For low-carbon steels, the minimum dome height occurs at a width of approximately 124 mm (4.9 in.). This can also be used as an approximation for other materials. Increments in test specimen width of  $\pm 3$  mm ( $\pm 0.12$  in.) are sufficiently close.

It has been found that for specimens lubricated lightly with a wash oil, the dome height increases with decreasing hold-down force below about 250 kN (28 tonf). This is attributed to the drawing-in of the flange. Therefore, a hold-down force of at least 250 kN (28 tonf) should be used. The limiting dome height is taken as the height at which the maximum load occurs.

Testing has shown a correlation between the limiting dome height test and production stamping performance (Ref 57). Some problems have been encountered with test reproducibility over a period of time and among different test facilities (Ref 58). Numerous attempts have been made to determine a correlation between the limiting dome height test and mechanical and forming property measurements. The dome height depends on the ability of the material to distribute strain and on the limiting strain level and would therefore be expected to correlate with the total elongation. Correlation for a range of different materials has been reported (Ref 59).

The specimens used in the limiting dome height test can be sheared or blanked from the sheet sample, and the test can be performed rapidly on equipment that automatically measures the dome height at the maximum punch load. The test has been widely used for both production control and research applications.

## OSU Test

The LDH test has been widely used, but as mentioned in the prior section, has some problems with reproducibility, which can make interpretation of test results difficult. The primary reason for this lack of consistency is that the hemispherical geometry of the tooling causes both spatial and temporal variation in strain during the test (Ref 60–62). Only a narrow window of opportunity exists within which to obtain a plane-strain fracture. For example, changing friction conditions slightly will result in different degrees of draw-in of the unclamped sides of the blank, causing different strain states at failure.

After considering both the positive and negative attributes of the LDH test, a new formability test was developed at The Ohio State University (Ref 63–65). This test, named the OSU test, uses a cylindrical punch and dies with a lockbead to stretch a wide blank to failure (Fig. 23).

The punch height at failure is an index of formability, as in other stretch formability tests. The test is quick and simple to perform because only one specimen width is required (typically about 5 in.) to obtain a plane-strain failure. The strain path remains at or near plane strain throughout the test, which improves test consistency significantly compared with LDH (Ref 63, 65). This contrasts with the LDH test geometry, which can produce a large range of strains, from near uniaxial tension to balanced biaxial tension (see the section “Forming Limit Diagrams” in this article). In this sense, the LDH tooling is quite versatile; however, for rapid and consistent evaluation of sheet metal stretch formability, as needed for quality assurance in a factory environment, the OSU test is a good option.

**Hole Expansion Test.** A flat sheet specimen with a circular hole in the center is clamped between annular die plates and deformed by a punch, which expands and ultimately cracks the

Fig. 23 Schematic of the OSU formability test. Source: Ref 65

edge of the hole. Flat-bottomed hemispherical and conical punches have been used, and in some cases die plates have been equipped with lock beads to prevent drawing-in of the flange. The punch should be well lubricated and should have a large profile radius. A spacer can be used between the punch and the sample, as in the Marciniak test. Figure 24 illustrates the hole expansion test using a flat-bottomed punch.

The test is terminated when a visible crack is observed, and the hole expansion is expressed as the percentage of increase in hole diameter:

$$\text{Hole expansion (\%)} = \frac{100(D_f - D_0)}{D_0} \quad (\text{Eq 25})$$

where  $D_0$  and  $D_f$  are the initial and final hole diameters, respectively.

The results of several hole expansion tests on eight different types of steel are reported in Ref 66. Square specimens measuring 203 mm (8.0 in.) on each side with a 25 mm (1.0 in.) diam punched hole, a 101.6 mm (4.0 in.) diam hemispherical punch, and die plates with a 2 mm (0.08 in.) radius lock bead were used. The measured hole expansion ranged from 24 to 82% for steels with yield strengths ranging from 253 to 537 MPa (36.7 to 77.9 ksi).

In most cases, removing the burr and cold-worked metal from the edge of the punched hole increased the hole expansion considerably. The hole expansion also increased with increasing total elongation and  $r_m$  value and decreased with increasing tensile strength (which was anticipated because total elongation decreases with increasing tensile strength). Inclusions were observed in crack locations, and inclusion shape control improved hole expansion performance.

### Drawing Test

**Swift Cup Test.** The most commonly used test for deep drawability is the Swift cup test. Circular blanks of various diameters are clamped in a die ring and deep drawn into cups by a flat-bottomed cylindrical punch. The standard tooling for this test is shown in Fig. 25. Drawability is expressed as either the limiting draw ratio (LDR) or the percentage of reduction. The limiting draw ratio is the ratio of the diameter,  $D$ , of the largest blank that can be successfully drawn to the diameter,  $d$ , of the punch:

$$\text{LDR} = \frac{\text{maximum blank diameter}}{\text{punch diameter}} = \frac{D}{d} \quad (\text{Eq 26})$$

Percentage of reduction is defined as:

$$\text{Percentage of reduction} = \frac{100(D - d)}{D} (\%) \quad (\text{Eq 27})$$

Cup height,  $h$ , is approximately (Ref 67):

$$h = \frac{(D^2 - d^2)}{4d} \quad (\text{Eq 28})$$

An alternative method for determining the limiting draw ratio uses blanks of a single diameter, which is less than the critical diameter in the standard test (Ref 68). The blanks are drawn to the maximum load, which usually takes place before 50% of the draw has occurred. The clamping force is then increased to prevent further drawing-in of the flange, and the load is increased to the point of fracture. The limiting blank diameter (LBD) is defined by:

$$\text{LBD} = \left[ \frac{\text{fracture load} \cdot (\text{blank diam} - \text{die diam})}{\text{maximum drawing load}} \right] + \text{die diam} \quad (\text{Eq 29})$$

The limiting draw ratio is given by:

$$\text{LDR} = \frac{\text{LBD}}{\text{punch diameter}} \quad (\text{Eq 30})$$

This method has been shown to correlate well with the standard test for a range of materials of widely different drawability (Ref 68).

The limiting draw ratio increases with normal anisotropy ( $r_m$ ) and thickness, particularly at the low ends of the ranges for these variables, but is not sensitive to the  $n$  value (Ref 69). The limiting draw ratio also increases as the punch profile radius increases up to about eight times the sheet metal thickness, as the die profile radius increases up to about 12 times the metal thickness, and as the punch speed increases. The height of the ears formed in this test is proportional to the  $\Delta r$  value.

Too low a blankholder force may cause wrinkling, and too high a blankholder force may cause fracture at the punch profile radius. The die rings should be well lubricated, but the punch should not be lubricated. By not lubricating the punch, the amount of stretching that occurs over the punch profile radius and the tendency for splitting to occur at this location are reduced.

### Stretch-Drawing Tests

Many forming operations involve stretching and drawing; for example, square cups have drawn corners and stretched sides. The ratio of stretching to drawing in an actual part can be measured by a shape analysis technique (Ref 70).

Fig. 24 Schematic of the hole expansion test with a flat-bottomed punch

A line is drawn from a reference point (for example, the center of the blank) to the edge of the blank, through the critical forming area. After forming, the ratio of the increases in length of this line inside and outside the initial die contact line is taken as the ratio of stretching to drawing. Two tests are commonly used for stretch-drawing: the Swift round-bottomed cup test and the Fukui conical cup test.

**The Swift round-bottomed cup test** resembles the Swift flat-bottomed cup test described previously. However, the top of the punch is hemispherical, which causes stretching in the center of the specimen in addition to the drawing-in of the flange to produce the wall of the cup.

This test was used to evaluate 50 different steels with a 50 mm (1.97 in.) diameter punch and 127 mm (5.0 in.) diameter specimens and with a 65 mm (2.56 in.) diameter punch and 165 mm (6.5 in.) diameter specimens (Ref 71). Hold-down forces of 490 and 981 N (110 and 220 lbf), respectively, were used at a test speed of 1 mm/s (0.04 in./s). Both sides of the specimens were lubricated with thin polyethylene sheet.

The end point of the test is determined by observing fracture visually or by detecting a drop in the punch load. Multiple regression analysis of the test results showed that the cup height at fracture increased linearly with increases in the  $r_m$  value,  $n$  value, and metal thickness.

To determine the correlation between performance of the steels in the stretch-drawing test and in actual parts production, 4 automotive stampings were made, using 12 different steels for each. The stampings had stretch-to-draw ratios ranging from approximately 1 to 5 to 2 to 1, and minor-to-major strain ratios in critical areas ranging from  $-0.3$  to  $+0.45$ . The correlation coefficients between the test and stamping results had an average value of 0.92 and ranged from 0.89 to 0.94 (a value of 1.00 indicates perfect correlation). In another trial on a stamping with a stretch-to-draw ratio of 4.5 to 1, the test results did not correlate. These tests indicate that for parts that involve both stretching and

Fig. 25 Standard tooling for the Swift flat-bottomed cup test

drawing, without excessive stretching, the Swift flat-bottomed cup test is useful as a quality control tool.

**Fukui Conical Cup Test.** In the Fukui conical cup test, circular specimens punched from a sample of sheet metal are deformed into conical cups by means of a 12.5 to 27 mm (0.5 to 1.1 in.) diameter ball and tooling of the type shown in Fig. 26 (Ref 69, 72, JIS Z 2249). The ball size depends on the sheet thickness. The specimens are lubricated on the die side only. Lubrication on the punch side leads to tilting of the specimens. Specimens are centered and held in place by the hold-down ring and deformed to fracture by the punch.

The diameter of the base of the conical cup formed is measured and divided by the diameter of the original specimen to give the Fukui conical cup value. The end point of the test is not critical because the diameter of the cone does not change after fracture. A constant punch travel is usually used. When the test material has a high level of planar anisotropy (a high  $\Delta r$  value), the conical cup is asymmetric, and an average diameter must be determined. A high correlation between the Fukui conical cup value and the product of the average  $n$  value and the average  $r$  value has been reported for low-carbon steels (Ref 69).

An alternative method has been developed for performing this test (Ref 50). The punch travel between the initial contact with the specimen and the onset of a drop in the punch load, which coincides with the formation of a visible neck, is measured and used instead of the ratio of the diameters. This value, known as the formability index, correlates with the uniform elongation and therefore with the  $n$  value for low-carbon steels.

## Wrinkling and Buckling Tests

Two principal types of tests are used for wrinkling and buckling: the conical cup wrinkling test and the Yoshida buckling test. The conical cup wrinkling test is similar to the Swift flat-bottomed cup test but uses a punch that is much smaller than the die opening. Consequently, the cup wall is conical and is not in contact with the punch. Under some conditions,

wrinkles form in the cup wall. In the Yoshida buckling test, a flat, square specimen is stretched slightly in the diagonal direction, and the height of the buckle that is formed is measured (Ref 73).

**Conical Cup Wrinkling Test.** A circular blank is clamped between annular dies and deformed by a flat-bottomed punch with a diameter that is typically about 75% of the internal diameter of the die. This procedure is illustrated in Fig. 27. At very low levels of hold-down force, wrinkling occurs in the flange. At higher levels, flange wrinkling is suppressed, but wrinkling occurs in the unsupported wall. This is caused by compressive stresses in the circumferential direction (hoop stresses) that are due to the local reduction in diameter as drawing progresses. For example, with a 75 mm (2.96 in.) diameter punch and a 100 mm (3.94 in.) diameter die, the top of the wall has a diameter of 100 mm (3.94 in.). If the cup depth is doubled, the original top of the wall becomes the new midpoint and must decrease in diameter to 87.5 mm (3.44 in.).

At high levels of blankholder force, the tensile stresses in the radial direction in the wall prevent the formation of wrinkles, and fracture at the punch or die radius becomes the limiting factor. The maximum cup height occurs at the intersection of the wall wrinkling and fracture limits, as shown in Fig. 28.

The results of experiments on several types of steel with different thicknesses and tooling of various dimensions have been reported in Ref 13 and 74. Wrinkling occurred in the unsupported

wall when the true compressive hoop strain exceeded a certain value for each level of the tensile radial strain for all tooling geometries and forming conditions. The critical wrinkling strains were plotted on the forming limit diagram, as shown in Fig. 29.

Attaining the critical wrinkling strain is strongly influenced by the dimensions of the specimen and tooling, lubrication, and the hold-down force. Changes in these variables that reduce the radial stress (that is, an increase in the die radius, improved lubrication, or a reduction in the blank diameter or the hold-down force) increase the tendency toward wrinkle formation.

Materials properties that affect wrinkling in the conical cup test are the  $r_m$ ,  $\Delta r$ , and  $n$  values and the ratio of the flow stress to the elastic modulus. A high  $r_m$  value and low  $\Delta r$  value reduce wrinkling, which initiates in the directions of lowest  $r$  value. A high  $n$  value enables the hold-down force to be increased, which increases the radial force and reduces wrinkling. A low flow-stress-to-elastic-modulus ratio also reduces wrinkling.

**Yoshida Buckling Test.** A flat, square specimen is gripped at opposite corners and pulled in tension in the diagonal direction, as shown in Fig. 30 (Ref 73, 75). The standard

Fig. 26 Schematic of the Fukui conical cup test. Source: Ref 62

Fig. 27 Schematic of the conical cup wrinkling test

Fig. 28 Wrinkling and fracture limits in conical cup drawing. Source: Ref 67

Fig. 29 Combined forming and wrinkling limit diagram. Source: Ref 68

Fig. 30 Schematic of the Yoshida buckling test. Source: Ref 67

specimen is 100 mm (3.94 in.) square with 41 mm (1.6 in.) wide grips and a gage length of 75 mm (2.95 in.). The buckle height is measured over a 25.4 mm (1.0 in.) width at the center of the specimen.

Nonuniform stresses are generated in the specimen, and these stresses cause a buckle to form in the center along the direction of loading. The height of the buckle at a given elongation, for example 2%, is used as the measure of buckling.

Several investigations have been conducted on the correlation between buckle height and test material properties. The Yoshida buckling test and a conical cone wrinkling test (using a hemispherical punch) were performed on several ferrous and nonferrous materials in different tempers (Ref 76). A direct correlation for both tests between the buckling or wrinkling height and the yield strength, an inverse correlation with the work-hardening exponent, and a lack of correlation with the normal anisotropy were reported. The Yoshida test was not successful for aluminum because the specimens fractured before buckling.

The Yoshida test was performed on 31 steels of different types and thicknesses, and correlations between the slope of the buckle height versus elongation curve, which is easier to determine than the height at a particular elongation, and the yield strength and the ratio of yield strength to tensile strength were obtained (Ref 14). An inverse correlation with the instantaneous (2%) strain-hardening exponent and a lack of correlation with the uniform elongation and normal anisotropy were also noted.

### Correlation between Simulative Tests and Materials Properties

Quantitative correlations between the results of simulative tests and select tensile properties have been determined for the Olsen cup, Swift flat-bottomed cup, and Fukui conical cup tests (Ref 50) and for the Swift round-bottomed cup test (Ref 71). In the first correlation, 48 materials were tested, including aluminum-killed, rimmed, and stainless steels and aluminum alloys in various tempers (Ref 50). Tensile properties included the directionally averaged percentage of total elongation,  $\bar{\epsilon}_T$ , to indicate the stretchability, and the normal anisotropy,  $r_m$ , to indicate drawability. The following relationships and correlation coefficients were obtained:

Test parameter	Relationship	Correlation coefficient
Olsen cup height/ punch diameter	$0.217 + 0.00474 \bar{\epsilon}_T + 0.00392 r_m$	0.925
Limiting draw ratio (Swift)	$1.93 + 0.00216 \bar{\epsilon}_T + 0.226 r_m$	0.835
Formability index (Fukui)	$0.525 + 0.0134 \bar{\epsilon}_T + 0.207 r_m$	0.757

The Olsen test involves a much greater ratio of stretching to drawing than the Fukui test, which

in turn involves a much greater ratio than the Swift flat-bottomed cup test.

In the second correlation, 50 different steels were tested (Ref 71), and the results were correlated with the average  $n$  and  $r$  values and thickness,  $t$ , as:

$$\frac{\text{Swift round-bottomed cup height}}{\text{blank diameter}} = 0.0830t + 0.679\bar{n} + 0.0594r_m - 0.036 \quad (\text{Eq 31})$$

### Forming Limit Diagrams

A traditional forming limit diagram (FLD) indicates the limiting strains that sheet metals can sustain over a range of major-to-minor strain ratios. Two main types of laboratory tests are used to determine these limiting strains. The first type of test involves stretching test specimens over a punch or by means of hydraulic pressure—for example, the hemispherical punch method. This produces some out-of-plane deformation and, when a punch is used, surface friction effects. The second test produces only in-plane deformation and does not involve any contact with the sample within the gage length.

The first type of test has been used much more extensively (Ref 6, 77–79) than the second and provides slightly different results (Ref 33, 80). Good correlation has been obtained between FLDs determined in the laboratory and production experience.

**The hemispherical punch method** for determining forming limit diagrams uses circle-gridded strips of the test material ranging in width from 25.4 to 203 mm (1.0 to 8.0 in.) that are clamped in a die ring and stretched to incipient fracture by a 102 mm (4.0 in.) diam steel punch (Ref 77, 79). The narrowest strip fractures at a minor-to-major strain ratio of about  $-0.5$ , which is comparable to that obtained in a tension test. As the strip width is increased, the strain ratio passes through plane strain toward positive values for a full-width specimen. Further increases in the ratio to a maximum value of  $+1.0$  (balanced biaxial stretching) are achieved by using progressively improved punch lubrication (oiled polyethylene, oiled neoprene) and by increasing thicknesses of polyurethane rubber between the sheet and the punch.

The strains are measured in and around regions of visible necking and fracture. The forming limit curve is drawn above the strains measured outside the necked regions and below those measured in the necked and fractured regions, as shown in Fig. 31.

**In-plane determination** of the forming limit diagram can be achieved by using the uniaxial tension test, rectangular sheet tension test, or Marciniak biaxial stretching test with elliptical and circular punches, as described earlier in this article. The forming limit curve can be determined over the full range of strain ratios, without

introducing any out-of-plane deformation. A comparison of the in-plane and punch methods showed close agreement for negative strain ratios and slightly higher values in the punch test at plane strain and for positive strain ratios (Ref 33).

### Circle Grid Analysis and Use of FLDs

Circle grid analysis is a useful technique for ensuring that a die is adequately prepared for production and for diagnosing the causes of necking and splitting failures in production (Ref 81, 82). The forming limit diagram for the type and gage of work material selected must first be obtained. Arrays of small diameter (2.5 mm, or 0.1 in.), evenly spaced circles are printed or etched on several blanks in the critical strain regions, preferably in the same location on each blank. Some of the blanks are formed into parts, and the major and minor axes of the deformed circles are measured in the critical locations. The critical strain regions of the part are identified by visual observation of necking or splitting, or by previous experience with similar parts. The local strains are then calculated from the measured dimensions and plotted on the forming limit diagram.

If the maximum strains measured are close to or above the forming limit curve (FLC), problems with the tooling, lubrication, blank size or positioning, or press variables are indicated, whether necking or splitting actually occurs. Fluctuations that occur in operating conditions and in the properties of the work material over a production run will eventually cause failure if the material is strained to its full capacity. If the greatest levels of strain in the stamping are more than 10% below the FLC, the dies are considered “green,” or safe. Many companies require this type of analysis, proving that the new stamping dies are capable of producing a part with strain levels in the “green” zone of the FLD, before buying off on the dies (Ref 83). When new dies cause levels of strain between 0 and 10% below the FLC, this is considered a “yellow” zone, where caution requires further development of either the dies themselves, the drawbeads, or other process conditions including lubrication. Any strain readings that exceed the FLC indicate a “red” condition, where the likelihood of failure is high if the dies are not modified prior to being used for production.

The material used in die tryout should have typical, or slightly lower, forming properties than the production material. The use of superior material may indicate an adequate forming safety margin that will disappear when a more typical or lower formability material is used. It is good practice to form a few gridded blanks of a standard (nonaging) reference material periodically during a production run to determine the trends in the maximum strains. If the strains are approaching the maximum limits, corrective measures can be taken before any actual failures occur.

A nonexhaustive list of industrial applications of the FLD includes (Ref 84):

Visual display of the cause of a problem	Tight radii Restrictions Insufficient punch-die clearance Blank too big
Strain comparisons	Mirror image stampings Before and after changes Last one shutdown, first one startup
Setting dies	Press lines, types and speeds Die location Ram adjustments
Guide modifications	Detect changes Rapid 2-blank method Sensitivity to changes Shop records
Strain history	Source of problem Breakdown sequence Status at shutdown
Monitor production runs	Die wear Sudden breakage Status at breakdown
Initial specifications	Material Lubrication Die release
Experimental changes	Material Lubrication Die modifications Press adjustments
Education	Apprentices New material New processes

**Circle Grids.** Many types of circle grid patterns have been used, such as square arrays of contacting or closely spaced noncontacting circles and arrays of overlapping circles. The contacting and overlapping circles provide improved coverage but are more difficult to measure manually. With small, closely spaced circles, it is possible to determine strain gradients accurately, provided the circles are not too small for accurate measurement. Circles with 2.5 mm (0.1 in.) diameters have been found to be a good size. Both open and solid circles have been used successfully, and automatic systems have been developed for measuring both types.

**Applying Circle Grids to the Blanks.** The circle grids can be applied to the blanks by a printing or photographic technique or by electrochemical etching. Printed and photographically applied circles are easily damaged and tend to rub off in areas contacted by the dies. This has led to general acceptance of etched circles.

In the electrochemical etching process, an electric stencil with the required grid pattern is placed on the blank and covered with a felt pad soaked in an etching solution. An electrode is placed on the pad, and low-voltage (up to 14 V) current is passed between the electrode and the blank for a short time, usually less than 1 min. This produces a lightly etched and oxidized pattern on the surface of the blank. The stencils, etching solutions, and power supplies for this process are commercially available. Different metals require different solutions, levels and types of voltage, and etching times.

**Measuring Strains from Deformed Circles.** Deformed circles can be measured

Fig. 31 Strain measurements and forming limit diagram for aluminum-killed steel. Source: Ref 76

manually by means of dividers and a ruler, graduated transparent tapes, or a low-power microscope with a graduated stage. Automatic systems, known as grid circle analyzers, have also been developed for measuring the dimensions of the circles and calculating and displaying the major and minor strains (Ref 85-87).

In regions of high curvature, the most accurate method of measurement is use of the transparent tape because it follows the contour of the part and measures the arc length, while the other methods measure the chord length. The tapes have a pair of diverging lines graduated to give direct readings of the strain, as shown in Fig. 32.

Fig. 32 Transparent tape measurement of deformed circles. Source: Ref 78

Grid circle analyzers use a solid-state digital array camera with a built-in light source, a minicomputer, keyboard, cathode-ray tube (CRT) display, and printer. An image of a given deformed circle is displayed on the CRT, and a

least squares curve fitting program selects the most suitable ellipse, which is displayed simultaneously. The major and minor strains, computed from the equation for the ellipse and the diameter of the original circle, are displayed on the screen and printed. A typical layout for the equipment is shown in Fig. 33.

### Drawbead Forces

It is common practice in production stamping operations to control the movement of the edges of the blank into the die cavity by means of drawbeads placed in the blankholder. These consist of a semicylindrical ridge in the upper part of the blankholder and a corresponding groove with rounded shoulders in the lower part, or a similar but opposite configuration. The drawbeads cause the periphery of the blank to bend and straighten three times as it passes through each bead, as shown in Fig. 34.

The repeated bending and straightening produces a restraining force in addition to that caused by surface friction. A method has been devised for measuring the restraining force due to deformation, independently of the effects of friction, using a drawbead simulator with low-friction rollers instead of a fixed bead and groove (Ref 88, 89). A second drawbead simulator with nonrotating parts can be used to measure the combined effects of friction and deformation. Figure 35 shows both types of simulators.

Strips of 0.75 to 1.00 mm (0.03 to 0.04 in.) thick and 50 mm (1.97 in.) wide rimmed and aluminum-killed steels and two aluminum alloys were tested using simulators and a universal testing machine. The contribution from deformation to the total restraining force depended on the lubricant used and ranged from an average of 60% with poor lubrication to 85% with very good lubrication. The required clamping forces, surface strains in the workpiece at various locations in the drawbead simulators, effect of drawbead radius, and effect of rate of testing were also investigated.

## Improvements to Forming Limit Diagram Technology

### Enhanced Forming Limit Curve Effect

The bending and unbending that occurs when a sheet metal is pulled through a drawbead has been shown to result in measured strain values that are misleading in terms of material formability. Experiments conducted by the Auto/Steel Partnership have shown that thinning strains caused by bending and unbending deformation, either through drawbeads or over tight punch and die radii, are only 40% as damaging as uniform thinning caused by pure stretching (Ref 83). This work resulted in a strain correction that is used to determine a new, correct forming limit. The strain correction is called "bead correction factor" (BCF) and is given by the simple

relationship:

$$BCF = 60\epsilon_t \quad (\text{Eq 32})$$

where  $\epsilon_t$  is the true thinning strain that occurs as sheet metal passes through a drawbead, or through a drawbead and die radius combination. This corrective factor is subtracted from the measured major strain so that only 40% of this strain should be used to determine forming severity. The practical advantage of using this correction lies in being able to quantify the true forming severity of material undergoing bending and unbending so that the results of die tryout experiments can be interpreted properly. In the past, strain levels in a sheet stamping may have exceeded the FLC for the material being tried but did not result in a failure. This result was problematic because all areas of the stamping needed to be in the "green" zone of the FLD in order for the tryout to be successful. Now this correction provides the press shop with a proven method of interpreting the strains produced at locations in a sheet stamping where material has passed through a drawbead or where material has passed over a sharp die radius. Additional

information on the enhanced FLC effect can be found in Ref 83.

### Stress-Based Forming Limit Curves

One of the difficulties with the traditional FLC is that it is generated by straining sheet metal specimens along essentially linear strain paths. As a result, a traditional FLC may not capture the formability of complex forming operations, including many first-stage operations, but especially when two or three forming steps are required to make a part. The inaccuracy that results from making the FLC path-dependant may be overcome by using a stress-based forming limit criterion, as proposed in Ref 90. The traditional strain-based FLC is equivalent to the stress-based FLC when loading paths are linear, but not when they are nonlinear.

This new approach involves plotting the forming limit curve in stress space, rather than in strain space. An appropriate constitutive model must be used to convert strain values, which may be easily measured experimentally, into values of stress for the material being studied. While

concerns about the dependence of this method on the choice of constitutive model have been raised, it was shown that this approach produces robust results that converge to the same values for a given material and for a given model (Ref 91, 92). An example of a stress-based FLC for 2008-T4 aluminum is shown in Fig. 36, using a von Mises yield surface with a power law stress-strain relationship.

The path-independence of this approach is demonstrated in Fig. 36, where the FLC in stress space for the as-received 2008-T4 material is nearly the same as that for an equibiaxial prestrained 2008-T4. The increased measure of

accuracy gained by this new approach can be used to improve the predictions of finite-element simulations of forming processes, which up to now have employed mostly the traditional strain-based FLC as a criterion for necking failure.

### Lubricants

The use of lubricants is essential in most forming operations (see the article “Selection and Use of Lubricants in Forming of Sheet Metal” in this Volume). An effective lubricant provides the following advantages:

- Reduction or elimination of direct sheet metal to die contact and the associated wear and galling
- Control of friction
- More uniform distribution of strain and therefore an increase in the overall level of deformation
- Reduction of heating

Lubricants must meet many requirements to be used in a production operation, such as:

- Suitable viscosity over the ranges of temperatures and pressures encountered
- Chemical and physical compatibility with work and die materials
- Ease of application, removal, and disposal
- Compatibility with welding operations, sealants, and paint systems

No single lubricant is optimal for all types and rates of forming and all combinations of work and die materials. Rankings of lubricants change considerably for different types of operations and material combinations; this necessitates evaluation on an individual basis. Differences in the performance of lubricants are to be anticipated in view of the differences in surface composition, roughness, and texture of work and die materials and the different strain paths and rates of different forming operations. For example, some stretching operations involve local increases in area in excess of 100%, but in many drawing operations, a negligible or negative change in area occurs. In addition, the rate at which the work material slides over the dies varies widely. A simple test for evaluating lubricants measures the frictional force exerted on a lubricated strip of sheet metal when it is pulled between two rectangular blocks of die material. The force used between the blocks and the test rate can be varied. The number of strips that can be tested before the onset of galling provides an additional measure of the effectiveness of the lubricant. However, this test does not include some of the important aspects of actual forming operations, such as plastic deformation of the work material, the ranges of sliding speeds and rates of straining involved, die geometry (which influences the amount of residual lubricant in various locations as the operation progresses), and the heating that occurs in high-volume production operations.

The drawbead simulator described earlier is more realistic and has been used to measure friction forces with various lubricants (Ref 88, 89). Under most of the conditions tested, friction was described by Coulomb's law, which states that the friction force,  $F$ , is directly proportional to the normal force,  $N$ , between the contacting surfaces:

$$F = \mu N \quad (\text{Eq 33})$$

where  $\mu$  is the coefficient of friction. Coulomb's law did not apply at the highest contact pressure tested. The value of the coefficient of friction for mill oil, a poor lubricant, was found to be 0.17;

Fig. 36 Stress-based forming limit curve for as-received 2008-T4 and prestrained 2008-T4. Source: Ref 90

Fig. 37 Schematic of OSU friction test. Source: Ref 94

for the best lubricant tested—a soap-based lubricant—it was 0.06.

In addition, simulative tests can be used as lubricant evaluation tests. The production operation should be characterized in terms of the principal types of forming operations involved and their relative severities, and the appropriate simulative test selected. The Swift flat-bottomed cup test has been used extensively for the evaluation of lubricants for deep drawing, and the Swift round-bottomed and Fukui conical cup tests have been used for stretch-drawing operations. The 100 mm (3.94 in.) hemispherical dome test can be used for stretching operations. A more recent test developed at The Ohio State University (OSU friction test) is capable of ranking lubricants through experimental determination of the friction coefficient (Ref 64, 93–96). A gridded strip of metal is clamped and then stretched by a punch, as shown in Fig. 37.

Measurement of the grids after the experiment allows for calculating  $\epsilon_1$  and  $\epsilon_2$ , which may be used to determine the forces if the constitutive behavior of the material is known. Combining this information with the contact angle (which can be obtained from the punch height) allows for calculating the friction coefficient, which may then be used as an index to rank lubricants.

The various regimes of lubrication—that is, thick film, thin film, mixed, and boundary lubrication—and their characteristics are reviewed in Ref 95, which also discusses the limited validity of Coulomb's law, various methods for lubricant evaluation, and some of the current limitations in this area.

# Troubleshooting Formability Problems Using Strain Analysis

Daniel J. Schaeffler and Evan J. Vineberg, Engineering Quality Solutions, Inc.

STRAIN ANALYSIS is a technique to assess the degree of stamping process robustness as it relates to the sheet properties of the incoming blank used to form the part in question. The analysis is typically done on parts formed from known sheet properties, but it is possible to extrapolate the forming behavior when the steel properties are at the low end of the ordered grade and thickness. Strain analysis is also useful during tool development to help limit problems during production. Although parts on day one may “hold water,” strain analysis can highlight those areas that may need some tooling work to ensure that the ordered steel or aluminum grade and the forming process, together, are sufficiently robust to produce a split-free panel over the entire property range associated with the particular sheet material grade. Strain analysis can help determine if a change to a more formable grade or heavier gage is warranted to reduce the potential for splitting. Similarly, strain analysis can help determine if a less formable grade (which is typically less expensive) or lighter gage (also a cost-savings opportunity) can be used.

This article describes techniques that can help with troubleshooting production process discrepancies. If supposedly symmetrical areas on a given part are not behaving the same way (e.g., the left side splits but the right side works), strain analysis can help determine if the locations in question are actually forming the same way and undergoing the same deformation. These differences in strain distribution can then be used to determine the root cause of the observed performance differences.

Once a robust condition has been achieved at the beginning of production stamping (or during the production stamping life cycle), a “reference panel” can be established with the aid of strain analysis techniques. This reference panel documents all properties, settings, and conditions that produced a good panel, such that these parameters can be replicated if issues are encountered during production. Using the strain distribution information from the reference panel, strains/thicknesses at selected areas

can be checked intermittently during ongoing production. Tracking these data as a function of time can be used as a statistical process control and quality-monitoring tool, providing indication of part/process consistency as well as raising a “red flag” if something with the material, tooling, and/or process setup is going out of control.

The same strain-analysis techniques described in this article thus provide a useful and versatile tool that can be used in troubleshooting formability and process discrepancies throughout the entire tooling development and production stamping cycle: initial die tryout, tooling buyoff, home pressline die tryout, and ongoing production stamping.

## Strain Calculations

Strain calculations can be visualized using the circle grid method by picturing a circle on a surface of a flat blank. After the blank is formed, the circle from the flat blank will become an ellipse (unless deformation is not pure biaxial stretching). The longest dimension of the ellipse is the major axis, and the dimension perpendicular to the major axis is the minor axis. Knowing the exact dimension of the starting circle as well as obtaining an accurate measurement of the length of the major and minor axes

(Fig. 1) allows for the direct calculation of the engineering major and minor strains, where:

$$e_{ma} = \text{Major strain (\%)} = 100 \times \left( \frac{L_{ma} - L_i}{L_i} \right)$$

$$e_{mi} = \text{Minor strain (\%)} = 100 \times \left( \frac{L_{mi} - L_i}{L_i} \right)$$

The major strain is always positive and always greater than the minor strain. In the sketches shown in Fig. 2, the shape of the initial circle is shown as a dashed line. After forming, there are three possible descriptions of the shape of the resulting ellipse.

In this process of metal deformation, a unit of material maintains a constant volume before, during, and after forming. This allows for calculation of a thickness strain ( $e_t$ ), because the major, minor, and thickness strains in that unit of material multiplied together must equal 1, such that:

$$(e_{ma} + 1) \times (e_{mi} + 1) \times (e_t + 1) = 1, \text{ or}$$

$$e_t = \left[ \frac{1}{(e_{ma} + 1) \times (e_{mi} + 1)} \right] - 1$$

A nomograph of this is shown in Fig. 15 of the article “Formability Testing of Sheet Metals” in this Volume. As an example, consider a 0.100 in. diameter circle that was deformed into an ellipse with the longest dimension of 0.125 in., and

Fig. 1 Definition of major strain and minor strain

perpendicular to that, the ellipse measured 0.090 in.:

$$\begin{aligned}
 e_{ma} &= \text{Major strain (\%)} \\
 &= 100 \times \left( \frac{0.125 \text{ in.} - 0.1 \text{ in.}}{0.1 \text{ in.}} \right) \\
 &= 100 \times \left( \frac{0.025 \text{ in.}}{0.1 \text{ in.}} \right) = +25\% \\
 e_{mi} &= \text{Minor strain (\%)} \\
 &= 100 \times \left( \frac{0.09 \text{ in.} - 0.1 \text{ in.}}{0.1 \text{ in.}} \right) \\
 &= 100 \times \left( \frac{-0.01 \text{ in.}}{0.1 \text{ in.}} \right) = -10\%
 \end{aligned}$$

$$\begin{aligned}
 e_t &= \text{Thickness strain (\%)} \\
 &= \frac{1}{(e_{ma} + 1) \times (e_{mi} + 1)} - 1 \\
 &= \frac{1}{(0.25 + 1) \times (-0.10 + 1)} - 1 \\
 &= \frac{1}{(1.25) \times (0.9)} - 1 = \frac{1}{1.125} - 1 = 0.89 - 1 \\
 &= -0.111 = -11.1\%
 \end{aligned}$$

## Forming Limit Curves

Every sheet product has a limit to which it can be deformed before it splits. The maximum amount to which the material can be deformed before splitting is a function of not just the maximum major strain on a formed part but also the associated minor strain at each location as well. In experiments conducted since the late 1960s, numerous grades and thicknesses of sheet products have been deformed over a range of minor strain conditions (varying degrees of draw, plane strain, and stretch) to just before and just beyond failure. The strains on these parts were measured and plotted on a graph of major strain versus minor strain. The resulting curve defining the boundary between split-free and split conditions is called the forming limit curve (FLC).

Interestingly, the shape of the FLC is essentially the same for all sheet steel products. The

only thing that changes is where the FLC is plotted on the major strain versus minor strain graph. The location of the FLC is determined by the value of  $FLC_0$ , which is defined as the lowest point on the FLC and typically occurs in plane-strain deformation (when the minor strain is zero).

The  $FLC_0$  is a function only of initial sheet metal thickness (before forming) and  $n$ -value (strain-hardening exponent). As thickness and  $n$ -value increase, the  $FLC_0$  is greater and is therefore plotted higher on the graph.

Based on empirical data,  $FLC_0$  is calculated as:

$$FLC_0 = (23.3 + 360 \times t) \times (n/0.21)$$

where  $t$  is the sheet thickness in inches, and  $n$  is the  $n$ -value, and:

$$FLC_0 = (23.3 + 14.2 \times t) \times (n/0.21)$$

where  $t$  is the sheet thickness in millimeters, and  $n$  is the  $n$ -value.

Note that some versions of these equations show the coefficients to one or two additional decimal places. The added precision does not appear to affect the results significantly, and the equations in the aforementioned format are consistent with what is used within American Iron and Steel Institute and International Iron and Steel Institute documents written by Dr. Stuart Keeler, who first developed the FLC concept and strain analysis techniques in the 1960s and 1970s.

In the example in Fig. 3, the top FLC was generated using an  $n$ -value of 0.24 and a thickness of 0.90 mm (0.035 in.), for an  $FLC_0$  of 41.2%. The bottom FLC was generated using an  $n$ -value of 0.20 and a thickness of 0.80 mm (0.032 in.), for an  $FLC_0$  of 33.0%. Note that  $n$ -value has a much greater impact on the value of  $FLC_0$  than does thickness.

The shape and placement of the FLC for aluminum alloys, stainless steels, and some Advanced High Strength Steels like Transformation Induced Plasticity (TRIP) steels, cannot be represented by a simple curve or a universally applicable equation. For these products, a curve needs to be established for each grade and

thickness combination. Once this is done however, the same principles described in this article are applicable.

## Forming Limit Diagrams

A flat blank is deformed during stamping. The strains in this deformation occur both on the surface of the sheet (major and minor strain) as well as the through the thickness (thinning strain). These strains are primarily a function of the part design and the forming process. It is possible to measure these strains using relatively simple techniques described in this article.

Plotting these measured strains along with the FLC plot on a graph of major strain versus minor strain creates a forming limit diagram (FLD). An FLD provides a graphical indication of the stamping performance that can be expected when using the ordered grade of steel and when the stamping conditions (press, die, lubricant, etc.) that existed during the forming of the gridded blank are also present.

Measured strains that plot higher than the FLC are said to be in the failure zone (also known as the necking zone or red zone). These locations indicate areas that likely will exhibit localized thinning, necking, or splitting.

Locations having strains that plot close to, but not in, the failure zone are also of concern, because a slight change in a host of factors affecting forming (such as the normal day-to-day variability in stamping or lubricant conditions, or variations in the surface properties of the steel) can increase the strains just enough to push them into the red zone.

To reduce the likelihood that these subtle changes have a detrimental effect on the forming process, it is typically recommended that all measured areas on an FLD plot at least 10% lower than the FLC on the major strain axis. Locations that meet this criterion are said to be in the safe zone (or green zone) of the FLD. Locations that plot between the failure zone and the safe zone are said to be in the marginal zone (or

Fig. 2 Deformation mode as a function of minor strain

Fig. 3 Basic shape of the forming-limit curve, with  $FLC_0$  defined by the strain-hardening exponent ( $n$ -value) and sheet metal thickness ( $t$ )

yellow zone). Offsetting the FLC 10% on the major strain axis from the appropriate failure curve creates the marginal zone boundary with the safe zone.

## Safety Margin or Safety Factor

The vertical distance between the strain measured at a particular location and the strain on the FLC defines the major strain safety margin at that location. The lowest safety margin of all the locations is considered to be the overall safety margin of the part.

By definition, locations with major and minor strains that plot exactly on the FLC are said to have 0% safety margin (no room for error), and locations having safety margins between 0 and 10% are said to be in the marginal zone. A robust stamping process typically occurs when the measured strains plot in the safe zone, where all locations are more than 10% away from the FLC.

Greater values of  $FLC_0$  lead to plotting the FLC higher on the graph, which increases the vertical distance to the measured strains. This is the primary reason why greater safety margins are associated with steels of higher  $n$ -values. Increased  $n$ -value also lowers the peak strain severity and provides for a more even strain distribution, thereby also increasing the minimum strain safety margin.

More generous radii or better lubrication during forming can reduce the forming strains, and as such, these locations will plot lower on the FLD. This leads to increased safety margins as well.

In the example shown in Fig. 4, at a minor strain value of  $-20\%$ , the FLC major strain value is  $77\%$ . The vertical distance between point A, which plots as  $+50\%$  major and  $-20\%$  minor, and the FLC is  $27\%$ . This means that location A is in the safe zone with a  $27\%$  major strain safety margin.

At plane strain, where the minor strain is  $0\%$ , the FLC is at its lowest point, the  $FLC_0$ . In this example, for the material used ( $n = 0.24$ ,

$t = 0.90$  mm, or  $0.035$  in.), the  $FLC_0$  is calculated as  $41\%$ . Point B plots as  $+50\%$  major and  $0\%$  minor, which falls above the FLC and, as such, is in the failure zone with a major strain safety margin of  $-9\%$ .

At a minor strain value of  $+20\%$ , the FLC major strain value is  $53\%$ . The vertical distance between point C, which plots as  $+50\%$  major and  $+20\%$  minor, and the FLC is  $3\%$ . This means that location C is in the marginal zone with a  $3\%$  major strain safety margin.

## Types of Strain Analysis

There are two general types of strain analysis, known as thinning strain analysis and circle grid (or surface) strain analysis.

### Thinning Strain Analysis

Thinning strain analysis (TSA) is easier to perform and requires very little operator training. TSA can be done on any formed part, without special preparation of the blank or tools before stamping. TSA does not require as much stamping plant involvement and assistance as circle grid analysis (CGA). Production stamping schedules are less likely to be disrupted when a TSA is needed. TSA will also be used when it is not practical to place circle grids on a blank. Examples include parts stamped on a progressive die or in the central portion of a very large blank.

In addition, during die development of new parts, TSA is a useful tool to assess the effect of tooling changes when the minor strain has not changed from the previous CGA. An example of this would be when a radius is increased along a sidewall that is in plane strain (minor strain =  $0$ ). Knowing the minor strain and measuring the thickness allows for calculation of the major strain.

The concern is that this approach may indicate that this location is not safe (suggesting that the time and cost of tooling work may be warranted). In reality, the metal deformation may be in stretch mode, with an associated greater safety margin, reducing the need for tooling work because the part may actually be safe.

**TSA Technique.** The tools of the TSA technique include an ultrasonic thickness (UT) gage and a micrometer or some other measuring tool to determine a reference thickness. If it is possible to obtain a reading before forming, measure the thickness of the flat blank, using the reference micrometer, and calibrate the UT gage at this location. It is important to remember that the UT gage is sensitive to the type of base metal, coating, and nominal thickness. Therefore, every time there is a change in any of these conditions, it is important to perform this procedure to ensure the UT gage is properly calibrated for the particular subject material.

If the blank is not available before forming, use the micrometer to obtain a known reference thickness on the flat edge of the formed draw

panel (or some other flat stock of the same nominal thickness made of the same base steel and coating as the formed part). Calibrate the UT gage at this location.

After forming, measure the thickness at various regions on the formed part, using the UT gage. Focus on the critical areas, and determine the exact location of the thinnest area within a given region. If finite element analysis (FEA) has been performed on the part design/tooling development and the FEA package is available, it will generally include a map of potential "hot spots" that should be the first locations checked for thinning. Other locations should also be checked to confirm that the FEA package is an accurate representation of the current state of the part. During or after measurement, mark the locations on the panel where measurements were made, and photograph the part so it is clear as to which specific areas were analyzed.

After measurements, then calculate the percent difference between the formed part thickness reading and the initial blank thickness to determine the thickness reduction percentage, which is the thinning strain:

$$\text{Thinning strain (\%)} = e_t = \frac{\text{Formed part thickness} - \text{Initial blank thickness}}{\text{Initial blank thickness}} \times 100\%$$

Note that the initial blank thickness is not necessarily the same as what was measured in the previous calibration stage. Even though the edge of a formed draw panel may be flat, there may have been some thinning. Also note that the initial blank thickness is not necessarily the gage reported on the steel certification. The material certification may list only the minimum or nominal ordered thickness. Even if an actual thickness is reported on the certification, this was likely determined from the coil end at the quarter- or center-width position and may not be exactly representative of the blank used to form the analyzed part. Ideally, the initial blank thickness is determined from the specific blank used to form the analyzed part.

**Thinning Strain Calculation Example.** This example shows how thinning strains can be calculated and also illustrates the importance of knowing the actual flat blank material thickness in order to avoid discrepancies in interpretation of thinning strain results as being either "Acceptable" versus "Unacceptable" thinning conditions. Assumptions are:

- The specified nominal gage for a given part is  $0.80$  mm ( $0.032$  in.)  $\pm 0.02$  mm ( $0.0008$  in.).
- The thickness measured at a particular location is  $0.64$  mm ( $0.025$  in.).
- For this particular application, thinning strains below  $-20\%$  are considered "Acceptable" (or "Safe/pass"), and thinning strains exceeding  $-20\%$  are considered "Unacceptable" (or "Fail"). Thinning strains of

Fig. 4 A Representative forming limit diagram and 10% marginal zone

exactly  $-20\%$  are considered “Marginal” (or questionable).

If the initial blank thickness is known, the actual thinning strain can be directly calculated:

$$e_t(\%) = [(t_{\text{measured}} - t_{\text{initial}}) / t_{\text{initial}}] \times 100\%$$

If the actual initial thickness is not known, logical options for estimating the thinning strain include the nominal gage, the minimum specified gage, or the maximum specified gage. In the example described here:

- Initial thickness assumed to be the minimum of the allowed tolerance (gage =  $0.80 - 0.02 = 0.78$  mm), such that:  $e_t(\%) = [(0.64 - 0.78) / 0.78] \times 100\% = -17.9\%$ . Compared to the  $20\%$  maximum thinning criterion, this area is “Acceptable.”
- Initial thickness assumed to be “Nominal” (gage =  $0.80$  mm), such that:  $e_t(\%) = [(0.64 - 0.80) / 0.80] \times 100\% = -20.0\%$ . Compared to the  $20\%$  maximum thinning criterion, this area is “Marginal.”
- Initial thickness assumed to be the maximum of the allowed tolerance (gage =  $0.80 + 0.02 = 0.82$  mm), such that:  $e_t(\%) = [(0.64 - 0.82) / 0.82] \times 100\% = -22.0\%$ . Compared to the  $20\%$  maximum thinning criterion, this area is “Unacceptable.”

If the maximum allowable gage is used as the basis for assessing part-thinning status, areas appearing to exhibit “Unacceptable” thinning conditions may actually be “Acceptable” if the original initial blank thickness is within specification but substantially less than the allowed maximum. The risk is that some “Acceptable” areas may appear as “Unacceptable,” which could lead to more tooling work to bring everything to compliance.

Conversely, if the minimum allowable gage is used as the basis for assessing part-thinning status, areas appearing as “Acceptable” could actually exhibit “Unacceptable” thinning conditions if the initial blank thickness is again within specification but substantially greater than the allowed minimum. The risk here is that some “Unacceptable” areas may appear as “Acceptable,” which could lead to problems after the tooling is bought off and the part is in production.

### Circle Grid Application and Measurement

Circle grid strain analysis (CGSA or CGA) takes more operator training and requires application of the grid pattern on the flat blank before it is formed. CGA will provide a great deal of information on the forming of the part and can be used to project panel performance with a change in sheet metal properties.

Thinning strain analysis by itself is a useful quality-assurance tool to assess panel performance over time. A CGA is useful as an up-front analysis, done at hard tool buyoff and/or home line commissioning, to assess overall process

robustness as it relates to sheet metal properties. When there are forming problems in production, CGA can provide insight on the forming modes across the panel.

**Circle Grid Strain Analysis Technique.** The tools for CGA are:

- Ultrasonic thickness gage
- Micrometer or some other measuring tool to determine a reference thickness
- Electrolyte
- Stencil containing the grid pattern
- Felt pad
- Power source with grid-application device (rocker, roller, or grid wand)
- “Cleaner” (which, in reality, is a neutralizer)
- Calibrated Mylar (E.I. du Pont de Nemours and Company) strip with divergent “railroad” tracks
- Point dividers

In order to perform a CGA, one must have access to the flat blank before stamping. Measure and record the thickness of the blank as well as other descriptive information, such as dimensions and configuration (rectangular, trapezoid, developed, etc.).

**Application of Circle Grids to Blank.** Wipe off any oils that are on the blank (i.e., mill oil or prelube). A rag is often sufficient, and solvents are not necessarily needed. Do *not* use the aforementioned “cleaner” at this time. It is used after gridding to neutralize the acid contained within the electrolyte.

Next, determine which surface will be electrochemically etched with a grid of circles of known diameter on the blank. If it is an exposed part, the circles typically are on the exposed surface. For an unexposed part, the circles typically are on the surface that will be easiest to read once the part is formed (generally, the cavity side of the blank rather than the side that comes in contact with the punch).

Application steps are as follows:

- Put a light coating of electrolyte in the area that will be etched with a grid.
- Lay the stencil on top of that area. Smooth out any air pockets. This is crucial, because an air pocket will prevent transfer of a perfect circle.
- Lay a felt pad on top of the stencil. This felt pad should be saturated with the electrolyte.
- Connect the gridding device lead(s) to the power source. Connect the ground clip to the blank. If needed, connect the other end of the cable to the grid-application device.
- Set the amperage to approximately one-half to three-fourths of the way to the  $100\%$  setting.
- Pick up the grid-application device off the blank (or wherever it is placed). Turn the power on. Place the grid-application device on a given area on top of the felt pad (in the areas on top of the stencil) and gently rub it across that area a few times, then move to a different area until the area of the stencil has been covered. *Note:* Excessive pressure on the grid-application device is neither needed nor

desired. Too much force may have the tendency to shift the stencil.

- Turn the power off, and then put the grid-application device down.
- Gently lift one corner of the stencil to determine if the transfer is sufficient. If the transfer is lighter than desired, increase the amperage slightly, pick up the grid-application device, turn on the power, and repeat the grid-application process until an acceptable grid is produced. *Note:* Care must be taken not to shift the stencil when the operator “peeks” under one corner. If the stencil does shift, then a series of double circles will be produced that will be difficult to analyze. If the stencil does not shift, then the grid pattern should be quite readable, even though one corner has been lifted.
- Turn the power off, and then put the grid-application device down.

In this process, it is necessary to always turn the power on as the last step before gridding and turn the power off as the first step after gridding. If the grid-application device touches a metal surface with the power on, it will produce a spark. The resulting weld nugget may be large enough to interfere with forming. Also, the operator may receive an unpleasant shock if the metal edges of the grid-application device are touched when hands are covered by electrolyte. Wearing rubber gloves will help avoid the shock as well as protect the operator’s skin from the electrolyte and cleaner.

The process is repeated until the entire blank is covered with the grid pattern. The panel is then wiped with the cleaner (neutralizer) to prevent further etching from the electrolyte.

There is some concern that the electrochemically etched circle pattern may change the frictional characteristics of material pulling in across draw beads, thereby changing the formability characteristics of the overall forming process. Therefore, when gridding, try to estimate the location(s) of draw beads around the binder, and apply the grid pattern only inside the perimeter of the draw beads. Depending on the size of the blank/part and the nature of the binder development, the grid pattern should generally be applied to within 25 to 50 mm (1.0 to 2.0 in.) of the blank edges.

After application of the circle-grid pattern on the appropriate surface, relubricate the blank, using the correct lubricant specified for the part. Attempt to relubricate to a level similar to that seen on production coils (light, uniform coating; no large puddles). This protects the blank from rusting between the time it is gridded and the time it is actually formed, and also provides lubrication in the forming operation similar to that experienced with the specified production material under prescribed forming conditions.

**Forming of Blanks with Circle Grids.** Form the gridded blank using production-representative techniques, if possible. Ideally, the press should be warmed up, and several

satisfactory nongridded blanks have just been formed. Wipe any excess oils off the panel.

In the areas of interest, measure each circle (which are now ellipses). To narrow down the number of circles that need to be measured, use the UT gage to find the thinnest area. Measure the circle associated with this thinnest area. Each general section on a panel should be documented. Photograph the part so it is clear which areas were measured.

Plot the major and minor strains on the appropriate FLD. Different customers have different acceptance criteria. Examples include:

- All points are more than 10% safe on the FLD created for minimum  $n$ -value and minimum allowable thickness.
- All points are more than 10% safe on the FLD created for minimum  $n$ -value and actual thickness.
- All points are more than 10% safe on the FLD created for actual  $n$ -value and actual thickness.

**Measuring Strains Using a Calibrated Mylar Strip Ruler.** Accurate measurements of

**Fig. 5** Use of the Mylar strip to measure major and minor strains

**Fig. 6** Schematic representation of correct versus incorrect use of the Mylar strip

major and minor strains are crucial to obtaining the correct information on which to base forming-severity conclusions. A flexible Mylar strip ruler is the most common tool used to measure the deformation on electrochemically etched circles/ellipses. These Mylar strips are calibrated to provide direct readings of the percent strains for initial circles of a given diameter.

To measure the major strain, position the Mylar strip so the wedge-shaped scale is perpendicular to the ellipse major axis. Then, slide the scale until the wedge scale lines are centered on the ellipse etched lines. Read the engineering major strain directly from the scale (Fig. 5 and 6) with the following in mind.

- It is very important to have the diverging lines perpendicular to the major axis in making a correct measurement. Also, the diverging lines should be over the ellipse etch line, not outside or inside, for a correct measurement.
- Circles/ellipses to be read should be uniform in shape. A distorted ellipse (looking like an egg) is too close to the neck/fracture and will not provide the correct major and minor strain readings.
- The minor strain is measured in the same manner, rotating the scale accordingly.

**Measuring Strains Using Automated Grid-Reading Techniques.** In addition to the conventional Mylar strip approach to read circles/ellipses, there are a number of video-camera noncontact grid-reading systems available that offer data-logging capability, direct hookup to a laptop computer, and varying degrees of portability.

This approach does take some of the operator subjectivity out of the measurements, but the readings can be influenced by the available lighting, the clarity/crispness of the lines of the ellipse, the angle of the equipment relative to the surface of the part, and other system-specific issues. Still, under controlled conditions, this approach can be much faster than the Mylar strip method, especially when reading numerous data

points, such as what would be necessary to generate an FLC.

Whereas the more portable units can be used in field applications, for example, in a stamping plant setting, even the most rugged of these camera systems is still somewhat delicate and may be more appropriate for laboratory or benchtop applications rather than the typical environment encountered on the stamping plant floor.

## Circle Grid Analysis

**Example: Plotting Strains on a Forming Limit Diagram.** Surface strains measured at three locations on a part are shown in Fig. 7. These strains are then plotted on an FLD, which is the same one shown in Fig. 4.

Observe that the corner of the part in draw (location A: negative minor strain) is not near failure, because the measured strain plotted on the FLD is in the safe zone with a 27% major strain safety margin.

The sidewall of the part in plane-strain deformation (FLD center, location B: zero minor strain) exhibits a strain level located in the failure zone. That part location should exhibit either a neck or a split.

The location of the part in stretch (location C: positive minor strain), plotted on the right side of the FLD, is located in the marginal zone with a 3% major strain safety margin. The marginal zone signals that the part is near the onset of necking.

Also note that to go from the draw location, A, to the plane-strain location, B, (which changes the part from being very safe and robust to a location that will probably split) involves a measurement difference of just 0.5 mm (0.02 in.) (from 2.0 to 2.5 mm, or 0.08 to 0.10 in.) in the minor strain reading. This should reinforce how critical it is to accurately measure the strains.

**Failure Thinning Limit Curve.** The failure thinning strain is the through-thickness strain

**Fig. 7** Example of measured strains on a complex stamping. These strains are plotted on the forming limit diagram in Fig. 4, which was drawn assuming an  $n$ -value of 0.24 and a thickness of 0.90 mm (0.035 in.).  $e_{ma}$ , major strain;  $e_{mi}$ , minor strain. Dimensions given in inches

before the onset of a necking failure. A failure thinning strain can be calculated for each failure major and minor strain combination on the FLC using the equation:

$$e_t = \frac{1}{(e_{ma} + 1) \times (e_{mi} + 1)} - 1$$

Plotting these results against the minor strain values yields the thinning-limit curve (TLC) shown as the dashed curve in Fig. 8. The failure thinning strain under draw and plane-strain deformation is calculated using  $FLC_0$  as the major strain value and a minor strain value of zero:

$$TLC_0 = e_{tf} = \frac{1}{(FLC_0 + 1) \times (0 + 1)} - 1$$

The  $TLC_0$  (which is the border of the marginal and failure thinning strains) is based on  $FLC_0$ , as shown in the previous equation. Similarly, the border of the safe and marginal thinning strains of the TLC ( $TLC_M$ , where "M" stands for marginal) is based on  $FLC_0 - 10\%$ :

$$TLC_M = e_{tM} = \frac{1}{([FLC_0 - 10\%] + 1) \times (0 + 1)} - 1$$

Note that although a 10% safety margin is used for the FLC (10% on the major strain axis separates the marginal and failure zones on the FLC), this does not translate into 10% on the thinning strain axis separating the marginal and failure zones of the thinning limit diagram. This value is closer to 7% on the thinning strain axis and can be shown by  $TLC_0 - TLC_M$  in the previous equations.

From here, it is possible to calculate a failure thickness and a marginal thickness:

- **Failure thickness** = Initial blank thickness  $\times$  (1 + Failure thinning strain), or

$$t_f = t_0 \times (1 + e_{tf})$$

Fig. 8 Representative thinning limit curve, as derived from the corresponding forming limit curve

- **Marginal thickness** = Initial blank thickness  $\times$  (1 + Marginal thinning strain), or

$$t_M = t_0 \times (1 + e_{tM})$$

Areas thicker than the marginal thickness are said to be in the safe zone of the thinning limit diagram, while areas thinner than the failure thickness are in the failure zone of the thinning limit diagram. Areas in between the marginal and failure thickness values are said to be in the marginal zone of the thinning limit diagram.

It is possible to determine the formed part thickness at all locations, without needing a UT gage, by measuring the major and minor strains and using a similar equation to the previously mentioned one. Using the contour thinning strain calculated from the major and minor strain values measured at any given location, the corresponding part contour thickness is calculated as:

$$\begin{aligned} \text{Part contour thickness} \\ &= \text{Initial blank thickness} \\ &\quad \times (1 + \text{Contour thinning strain}) \end{aligned}$$

**Example: Failure and Marginal Thickness Determination.** When it is not possible to do a circle grid, the following information could be useful (albeit conservative) for monitoring performance. Knowing the minimum specified thickness and either the minimum specified or expected  $n$ -value, one can calculate a worst-case  $FLC_0$ . Then, the thinning limit under draw and plane strain conditions can be calculated using the FLC. A similar calculation can be done for the marginal zone by substituting  $(FLC_0 - 10\%)$ .

As an example, assume that the minimum ordered gage is 0.80 mm (0.032 in.) and the minimum allowable  $n$ -value is 0.20:

$$\begin{aligned} FLC_0 &= (23.3 + 14.2 \times 0.80) \\ &\quad \times (0.20/0.21) = 33.0\% \end{aligned}$$

The failure thinning strain is therefore:

$$\begin{aligned} TLC_0 = e_{tf} &= \frac{1}{(0.33 + 1) \times (1)} - 1 \\ &= \frac{1}{1.33} - 1 = -0.248 = -24.8\% \end{aligned}$$

If the initial blank thickness is 0.81 mm (0.032 in.), the thickness value where the part enters the failure zone in plane-strain and draw deformation is:

$$\begin{aligned} \text{Failure thickness} &= 0.81 \text{ mm} (1 + [-0.248]) \\ &= 0.81 \text{ mm} (0.752) = 0.61 \text{ mm} \end{aligned}$$

The marginal-zone boundary is determined in a similar manner. With the  $FLC_0 = 33.0\%$ , the marginal zone is at a major strain value of 23.0%. As such, the marginal thinning strain is:

$$e_{tM} = \frac{1}{(0.23 + 1) \times (1)} - 1 = -0.187 = -18.7\%$$

The thickness value where the part enters the marginal zone in plane-strain and draw deformation is:

$$\begin{aligned} \text{Marginal thickness} \\ &= 0.81 \text{ mm} (1 + [-0.187]) \\ &= 0.81 \text{ mm} (0.813) = 0.66 \text{ mm} \end{aligned}$$

This can be interpreted as meaning the part will be in the safe zone as long as all areas measure greater than 0.66 mm (0.026 in.).

It is important to remember that these values for marginal and failure thickness of 0.66 and 0.61 mm (0.026 and 0.024 in.), respectively, were generated based on a thickness of 0.81 mm (0.032 in.) for the initial blank. The marginal and failure thickness values will increase as the initial blank thickness increases.

Also note that these values are for plane-strain and draw deformation only. The part can actually be thinner than these values in stretch deformation and still be safe. However, if it is not possible to do a circle grid to determine the minor strain value to confirm if the part is in stretch mode, then a conservative approach is recommended, where the values calculated from the aforementioned methodology are used.

## Bead Correction Factor

Over the years, it has been observed that in areas where steel is bent and unbent around draw beads, split-free parts can be produced even though measured strains are deep in the failure zone. With these sections in the failure zone, unnecessary die work or material grade changes may have been done to bring these areas into the safe zone, whereas in actuality, these areas were sufficiently robust. In 2003, the Auto/Steel Partnership (A/SP) published the results of an extensive study on this phenomenon, along with a procedure to adjust the measured strain readings to bring them closer to the field observations (Ref 1). This discussion and the following example are adapted from the A/SP training manual.

**Example of Bead Correction Factor.** The bead correction factor (BCF) is computed from the amount of sheet metal thinning caused by bending and unbending. Ultrasonic thickness measurements of sheet metal entering and exiting the draw bead (or draw bead and die radius combination) easily permit computation of the BCF. The magnitude of BCF can be large enough to reduce the FLC severity rating of a die from red (failure) to green (safe). The procedure is shown as follows, with example values.

*Data required:*

- $n$ -value (0.218)
- Thickness at area of concern (0.0213 in.)
- Initial blank thickness (0.0321 in.)
- Thickness at entry side of draw bead (0.0305 in.)

Compute  $FLC_0$ :

$$FLC_0 = (23.3 + 360 \times t) \times (n/0.21) = 36.2\%$$

**Determine Major Strain.** Use either the major strain measurement on a gridded sample or convert from the UT value under plane-strain assumptions:

Thickness strain ( $e_t$ )

$$= \frac{\text{Formed part thickness} - \text{Blank thickness}}{\text{Blank thickness}} \times 100$$

$$\text{So that } e_t = \frac{0.0213 - 0.0321}{0.0321} \times 100 = -33.64\%$$

$$\text{Major strain } (\%) = e_{ma} = \frac{1}{(e_t + 1) \times (0 + 1)} - 1$$

$$\text{So that } e_{ma} = \frac{1}{[(-0.3364) + 1]} - 1 = 50.7\%$$

Compute as-measured safety margin:

- $FLC_0 = 36.2\%$
- Subtract as-measured major strain =  $(-50.7\%)$
- As-measured safety margin =  $-14.5\%$  (red zone)

Compute BCF:

- $BCF = 60 \times \ln(t \text{ of exit bead} / t \text{ of enter bead}) = 60 \times \ln(0.0213/0.0305)$
- $BCF = -21.5\%$

Compute corrected engineering major strain:

- As-measured major strain =  $+50.7\%$
- Add  $BCF = -21.5\%$
- Corrected major strain =  $+29.2\%$

Compute corrected safety margin:

- $FLC_0$  (step 1) =  $36.2\%$
- Subtract corrected major strain =  $(-29.2\%)$
- Corrected safety margin =  $+7.0\%$  (yellow zone)

**Techniques for Measuring Small Strains Distributed Over Large Areas.** For such parts as automotive outer skin panels (e.g., hoods, roofs, doors, quarter panels), performance characteristics such as strength for the finished part, dent resistance, and oil canning resistance are often key design concerns. These characteristics result from the cold work imparted in the forming process through the relatively small biaxial surface strains (typically on the order of 0 to 5% major strain by  $-2$  to 5% minor strain) induced over the large and fairly flat portions of the formed panels.

To quantify these effects, it is necessary to accurately measure these generally small strains. The ability to do so by using the conventional CGSA techniques described previously (using the pattern of electrochemically etched small circles of typically 2.5 or 5.0 mm, or 0.10 or 0.20 in., diameter) is quite limited, because the very small change in dimension of an already small circle is difficult to measure with any reliable degree of accuracy or precision.

Instead, a pattern of larger circles (typically 100 mm diameter) is mechanically scribed on those portions of the flat blank corresponding to the areas of interest/concern on the formed parts. With forming, the originally round circles become elliptical in shape (similar in nature to what happens in conventional CGSA). By determining the directions of the major and minor strain axes and measuring the extent of deformation along those axes, the distributed biaxial strain state across the face of these panels can be established.

There are two basic approaches to achieving careful and accurate readings of the small strains distributed over large areas. Key to both is how the circles are initially scribed on the flat blank. A circle template of the precise circle diameter can be used to scribe the circles, but this does not provide an indication of the circle center; the lack of the circle center location makes it extremely difficult to precisely determine the major and minor strain axes. A preferred circle-scribing technique involves (light) center-punching of each circle location, from which a needle-tipped compass is used to "swing" the circle of desired diameter.

Templates have been developed that can be used to measure the described biaxial surface strains. The template is essentially a calibrated spiral printed on a Mylar sheet that, when centered over the originally round circle and appropriately rotated, provides an instant readout of the respective major and minor strain values. One drawback to this technique is that it is necessary to ensure that the spiral template being used is either an original (created to accurate dimensions and indeed printed on Mylar) or has been checked against an original template. For purposes of convenience, these templates are often reproduced on clear transparency material on a copying machine, and this results in two possible sources of inaccuracy:

- The image generally increases or decreases in the process of copying. The difference is generally small but significant enough to compromise the accuracy of the measured strain reading.
- The extent of possible expansion or shrinkage of the template (depending on the nature of the transparency material used) can significantly compromise the measured results.

An alternative approach is to begin with the same center-punched scribed circles on the flat blanks. After forming, "reswing" a circle of the same initial diameter from each of the center-punched locations. Comparing the round, rescribed circle to the shape of the formed ellipse provides a graphic indication of the major and minor strain axes.

It is important to note that the major and minor strain directions do not necessarily need to align with the edges of a rectangular blank. The rescribing of the round circles after forming will make the true alignment of the major and minor strain axes immediately apparent. To merely assume the major and minor strain axes direc-

tions based on the blank shape will, in many cases, lead to a misleading and inaccurate indication of the true biaxial strain distribution across the face of a formed panel.

Once the major and minor strain axes have been identified, the respective major and minor strain values are determined by calculating the difference between the final respective ellipse axis measurement and the original circle diameter. The easiest way to do this is to use 100 mm diameter circles, a metric scale (marked off to the nearest half of a millimeter), and a magnifying visor (with approximately a  $5 \times$  magnification lens) to measure the ellipse axes. Doing so provides an all-but-direct readout of the respective major and minor strain values.

For example, with an initial circle diameter of 100 mm:

- Ellipse major axis = 104.5 mm, so major strain =  $4.5\%$
- Ellipse minor axis = 98.3 mm, so major strain =  $-1.7\%$

Circles of 5 in. diameter can similarly be used, but even by using an English-unit scale marked off in decimal divisions (0.10 and 0.01 in. divisions), some level of calculation will be required to convert the measured ellipse dimensions to corresponding strain values.

## TSA Application Examples

**Production Process Robustness and Tracking with the Reference Panel.** Once a robust condition has been achieved at the beginning of production stamping (or during the production stamping life cycle), a reference panel can be established, using strain analysis techniques. This reference panel documents as a "snapshot in time" all of the material and part characteristics, peak strain and strain distribution conditions, the tooling conditions, and the press and process operating conditions and parameters used in forming the sound part under robust processing conditions. The reference panel is particularly useful if forming difficulties are experienced at any point during ongoing production stamping. If the part now experiences increased breakage rates, wrinkles/buckles in the formed parts, reduced productivity rates, compromised panel integrity characteristics (strength, dent resistance, oil canning resistance, etc.), or surface issues (scratches, scoring, powdering/flaking of surface coatings, etc.), there is a set of known conditions that was able to produce a satisfactory part, and the settings can be reverted to those conditions.

The required documentation falls into three basic categories:

- Material
  - a. Complete mechanical properties (actual thickness, yield strength, tensile strength, total elongation,  $n$ -value,  $r$ -value,  $K$ -value)
  - b. Surface coating—type and coating weight

- c. Lubrication—type and amount (film thickness)
- d. Blank type (rectangular, trapezoid, developed) and dimensions
- e. Surface roughness characteristics
- f. Detailed strain and thinning analyses of the draw panel
- g. Documentation of breakdown panel characteristics (if available)
- Tooling conditions
  - a. Tooling surface characteristics—polishing, hardness, coating, and so on
  - b. Bead conditions—geometry, locations, dimensions, surface conditions, and so on
  - c. Engineering change level of the current die configuration
- Press and process parameters
  - a. Press number and type
  - b. Binder and punch tonnage conditions
  - c. Shims—locations and thickness
  - d. Detailed binder set draw-in measurements at key locations
  - e. Shut height
  - f. Press speed

If problems are experienced in the course of ongoing downstream production, the reference panel documentation is there as a benchmark to compare the current/problematic conditions to those known to yield a combination of sound and robust part and process. With this knowledge, it should now be possible to both identify the source of the difficulty and return to the favorable/desired material/tooling/process conditions. The onset of forming/process difficulties can be either sudden/abrupt (as, for instance, if wrong material is inadvertently run, or tonnage settings are grossly off) or more gradual in nature (as, for instance, the deterioration of panel quality/integrity over time with the slow wearing of draw beads with ongoing production). In either case, the reference panel documentation should provide significant help both in determining the source of the change and in restoring the favorable forming and processing conditions.

**Thickness Strain Analysis as a Statistical Process Control Tool.** Another useful and nondestructive application of thinning strain analysis is in statistical process control. Critical locations can be defined from structural requirements (determined from finite-element analysis, or FEA, or physical crash testing, for example) or from formability requirements (hot spots from FEA or hands-on strain analyses). A draw panel is then marked with the critical locations, and small circles are cut out of these critical locations. These cut circles should be big enough to accommodate the probe tip of a UT gage. The draw panel with cut holes is now a template for measuring critical locations and can be laid on top of any subsequent panel to ensure that the same areas are measured each time. If the part in question is made from a relatively large draw panel that is hard to maneuver, then the full draw panel template can be cut into smaller pieces, with one or more critical locations on each minitemplate.

Using the strain data for critical locations on a given draw panel (as established, for instance, in documenting the reference panel described previously), areas are cut from a typical draw panel to be used as templates overlaying the particular key locations of the draw panel.

On a prescribed schedule (once an hour, once a shift, beginning and end of each production run, etc.), a draw panel is taken off-line, and UT measurements are made, using the templates for each of the key locations. After the measurements are made and recorded, the panel can be returned to the rack and used for regular production requirements. Although it is possible to use a hand-held micrometer instead of a UT gage, it is more time-consuming, because the panel needs to be cut up into small enough pieces to measure, and as such, the panel is now scrap after the measurements are made and recorded.

Logging these data points and plotting them as a function of time provides an indication as to process stability. If, for whatever reason, something in the process is drifting out of control, the effects should show up as changes in the noted-versus-expected strain levels and distributions. Once such changes are observed, the reference panel can again be referred to in order to identify the source/nature of the material/tooling/process discrepancy, and to return to the prescribed/favorable conditions known to be capable of robustly producing quality parts.

**How Circle Grid Analysis Techniques Can Influence the Part Safety Assessment.** Based on the principle of volume constancy, from any given pair of major and minor surface strain measurements, it is possible to calculate a corresponding thinning strain. Also, from the determined thinning strain and the initial blank thickness, the remaining metal thickness at the location in question can be calculated. If all of the measurements were perfect, the calculated thickness would be identical to that determined using a (properly calibrated) UT gage. However, due to surface-strain circle measurement error combined with the inevitable slight variation in UT gage readings, the measured and calculated thickness values are rarely in absolute agreement. For all practical purposes, if these values are within  $\pm 3\%$  of each other, they are typically considered to be close enough.

The following is an account of an actual situation in which CGSA practices came into direct question, the outcome of the ensuing investigation having a direct and significant impact on the ultimate determination of the strain-state safety assessment of the respective panels.

**Example: Incorrect Method Used in Circle Grid Analysis.** Two steel suppliers had been sourced on opposite sides of an otherwise virtually symmetric major automotive body outer panel. Draw dies for the two panels were in similar stages of tooling development and die tryout when representatives from the two steel companies were asked to perform surface and thinning strain analysis of their respective parts.

The results of one company were called into question, with the tool shop asking why—with two symmetric but essentially identical dies and both in the same state of tooling development—the supplier would be reporting only a few areas as exhibiting “Marginal” strain conditions. At the same time, the other supplier, analyzing basically symmetrically located areas on the other side of the part, was reporting “Failure” and “Marginal” conditions at nearly every location analyzed.

Before even rechecking their own circle readings or checking the readings provided by the other source, representatives from the first steel company noted that the calculated thicknesses they had reported agreed closely with the area-by-area UT gage data they had recorded and reported. Upon checking the results reported by the other steel company, they noted widely varying agreement (or lack thereof) between their calculated and measured thickness results, with some differing by as much as  $\sim 20\%$ . This immediately suggested the likelihood that there was something discrepant in either the circle readings or UT gage results reported by the other steel company.

After verifying their own findings, representatives of the first steel company spot-checked readings reported by the other supplier. They found that, based on their reading and plotting of areas that the other supplier had documented earlier, areas that the other supplier had reported as “Failure” now typically appeared as “Marginal,” and areas reported earlier as “Marginal” now typically appeared as “Safe.” In order to reproduce the strain measurements and safety status indications reported by the other steel company, representatives of the first supplier determined that the earlier results had to have been made by determining both major and minor strains by measuring from outside edge to outside edge of the respective circles—a practice that is both incorrect and inaccurate. This is shown in the top schematic sketch in Fig. 9. Below that sketch are several alternative options for correct reading techniques.

In the schematic representation of this hypothetical example, it is seen that outside-to-outside edge yields strain readings of 40% major strain by  $-5\%$  minor strain, which plots as a “Marginal” condition. Reading the circle using any of the correct options yields major and minor strain readings of 30 by  $-10\%$ , which plots as “Safe.” Also shown in each case are the circle dimensions that would be measured if a very precise scale were used rather than the calibrated Mylar strip usually used to directly determine surface-strain values. The dimensional difference of the 0.100 in. diameter circle between the correct major strain reading of 30% and the erroneous 40% indication is seen to be just 0.010 in. (ten thousandths of an inch!). Similarly, the difference in circle-dimension measurements between the correct minor strain determination of  $-10\%$  and the incorrect indication of  $-5\%$  is just 0.005 in. (five thousandths of an inch!). These dimensional numbers,

Incorrect circle-reading technique

Outside-to-outside  
 $e_{ma} = 40\%$  (0.140 in.)  
 $e_{mi} = -5\%$  (0.095 in.)  
 (Marginal)

Note that inside-to-inside is also incorrect and would likely be close to:  
 $e_{ma} = 20\%$  (0.120 in.)  
 $e_{mi} = -15\%$  (0.085 in.)

Correct circle-reading technique options

Center-to-center  
 $e_{ma} = 30\%$  (0.130 in.)  
 $e_{mi} = -10\%$  (0.090 in.)  
 (Safe)

Inside-to-outside  
 $e_{ma} = 30\%$  (0.130 in.)  
 $e_{mi} = -10\%$  (0.090 in.)  
 (Safe)

Outside-to-inside  
 $e_{ma} = 30\%$  (0.130 in.)  
 $e_{mi} = -10\%$  (0.090 in.)  
 (Safe)

Table 1 Thinning percentages from UT gage measurements

Area	Thickness by UTG(a)		Percentage thinning, %
	mm	in.	
A	0.644	0.0253	19.5
B	0.576	0.0227	28.0
C	0.530	0.0209	33.8
D	0.654	0.0257	18.3

while generally not measured or reported, are highlighted here to illustrate that even the slightest error in circle reading can quite easily result in significant misrepresentation of the actual/correct strain safety status of a part being analyzed.

To further illustrate this situation, data as measured and reported by the second supplier and rechecked by the first supplier for four representative areas are summarized in Tables 1, 2 and 3. The actual thinning percentages, calculated by comparing the point-by-point UT gage readings to the initial blank thickness, are indicated in the last column of Table 1. For each of the supplier's reported respective circle readings, the corresponding thinning strains also can be calculated. These values are in turn compared to the actual thinning strains (Table 2). When based on the incorrect circle readings, wide variation in agreement between the actual and calculated thinning strains is noted (differences ranging between 3.4 and 17.7%). For the correctly measured circles, the actual and calculated thinning strains are in much closer agreement (differences ranging from -2.2 to +2.4%).

The respective circle-reading data for each of these four representative locations are plotted in the FLD presented in Fig. 10. Here, the initial results, based on the incorrect circle-reading practices, are shown with the letter identifications A through D. For each point, the correct/corrected results are indicated as A' through D', respectively. In each case, a consistent trend is noted: The major strain is reduced, and the minor strain shifts toward the left on the FLD. This, in turn, results in a significant increase in the indicated strain safety margin in each case (Table 3). With location A, for example, going from a "Failure" condition with strain safety margin of -19% to a "Safe" condition for A' with a strain safety margin of +17%. For location C, the indicated strain safety status does not change, even with the correction for circle-reading technique, and the strain safety margin is seen to go from -13% for the (incorrect) location C indication to -4% for the (corrected) indication for location C'—a 9% strain improvement in the apparent strain safety status. However, even this would indicate significant work remains to be done to achieve a "Safe" configuration at this particular location.

Conversely, if circles are measured by likewise incorrectly reading from inside edge to inside edge, the results can be similarly misleading, but in the opposite direction: Areas that

G	25	5	14	Safe
G′	35	10	7	Marginal

Fig. 11 Schematic representation of the effects of incorrectly measuring circles by reading from inside edge to inside edge

are actually “Marginal” could appear as “Safe,” and areas that are actually “Failure” could appear as “Marginal.” Unlike the previous situation where unnecessary die work could result, here areas legitimately requiring further die work

could be overlooked. Data for several examples of the potential problems resulting from incorrectly measuring circles by reading from inside edge to inside edge are summarized in Table 4 and shown schematically in Fig. 11. In this example, the strains measured by reading from inside edge to inside edge are shown as the unprimed locations (E, F, and G). The strains for circles measured using the correct reading technique (e.g., center-to-center) are shown as the respective primed locations (E′, F′, and G′).

*Inferences.* When performing CGSA, be sure to follow proper procedures, and be careful to ensure accurate circle measurement/strain data. Using incorrect reading techniques can result in either passing areas appearing as failure situations and/or failure conditions appearing as safe. Either case results in a grossly inaccurate indication of the actual panel strain safety status. In addition, the following practices will ensure accuracy:

- Use a UT gage, specifically calibrated for the particular material in question, to determine the actual remaining sheet metal thickness at each specific point being analyzed. Also, wherever and whenever possible, make every effort to ascertain the initial blank thickness of the actual material being used in the specific tryout activity.
- In order to ensure accuracy and consistency, cross-check the thickness values determined by UT gage measurement versus those calculated from the measured major and minor strain data. If there is significant discrepancy between the two, it is an indication that either the UT gage reading or the strain data are in error, and in either case, one should recheck both values.

# Constitutive Equations

Amit Ghosh, University of Michigan

CONSTITUTIVE RELATIONS for metal-working include elements of behavior at ambient temperature as well as high-temperature response. Because bulk forming is conducted over a wide range of temperatures and strain rates, it is best to review the low-temperature behavior first and gradually build in the effects of high-temperature response. In the following sections, equations are presented first for strain hardening and then for strain-rate-sensitive flow, with alternate sections on empirically determined properties, followed by models of constitutive behavior.

## Strain Hardening (Ref 1)\*

Several phenomenological models used to describe hardening are summarized in Table 1. The first three predict continued hardening, whereas the Voce models predict saturation as a stress,  $\sigma_s$ . Kocks' mechanistic model also predicts saturation (Ref 2). In fact, a plot of  $\theta$  versus  $\sigma$  presents a good graphical picture of the saturation stress. Kocks' model is based on dislocation interactions and predicts an early steady-state saturation behavior. Figure 1 (Ref 3) demonstrates the hardening behavior of 1100 aluminum deformed under several different modes. The hardening does not saturate but persists to high stresses at low hardening rate.

## Strain Rate Effects (Ref 4)\*\*

Usually, flow stress increases with strain rate, and the effect at constant strain can be approximated by:

$$\sigma = C \dot{\epsilon}^m \quad (\text{Eq 1})$$

where  $C$  is a strength constant that depends on strain, temperature, and material; and  $m$  is the strain-rate sensitivity of the flow stress. For most metals at room temperature, the magnitude of  $m$

is quite low (between 0 and 0.03). If the flow stresses,  $\sigma_2$  and  $\sigma_1$ , at two strain rates,  $\dot{\epsilon}_2$  and  $\dot{\epsilon}_1$ , are compared at the same strain:

$$\frac{\sigma_2}{\sigma_1} = \left( \frac{\dot{\epsilon}_2}{\dot{\epsilon}_1} \right)^m \quad (\text{Eq 2})$$

or  $\ln(\sigma_2/\sigma_1) = m \ln(\dot{\epsilon}_2/\dot{\epsilon}_1)$ . If, as is likely at low temperatures,  $\sigma_2$  is not much greater than  $\sigma_1$ , Eq 2 can be simplified to:

$$\frac{\Delta\sigma}{\sigma} \simeq m \ln \frac{\dot{\epsilon}_2}{\dot{\epsilon}_1} = 2.3 m \log \frac{\dot{\epsilon}_2}{\dot{\epsilon}_1} \quad (\text{Eq 3})$$

For example, if  $m = 0.01$ , increasing the strain rate by a factor of 10 would raise the flow stress by only  $0.01 \times 2.3 \approx 2\%$ , which illustrates why rate effects are often ignored.

However, rate effects can be important in certain cases. If, for example, one wishes to predict forming loads in wire drawing or sheet rolling (where the strain rates may be as high as  $10^4/\text{s}$ ) from data obtained in a laboratory tension test, in which the strain rates may be as low as  $10^{-4}/\text{s}$ , the flow stress should be corrected unless  $m$  is very small.

At hot-working temperatures,  $m$  typically rises to 0.10 or 0.20, so rate effects are much larger than at room temperature. Under certain circumstances,  $m$  values of 0.5 or higher have been observed in various metals. Ratios of  $(\sigma_2/\sigma_1)$  calculated from Eq 2 for various levels of  $(\dot{\epsilon}_2/\dot{\epsilon}_1)$  and  $m$  are shown in Fig. 2.

There are two commonly used methods of measuring  $m$ . One is to obtain continuous stress-strain curves at several different strain rates and compare the levels of stress at a fixed strain using Eq 2. The other is to make abrupt changes of strain rate during a tension test and use the corresponding level of  $\Delta\sigma$  in Eq 3. These are illustrated in Fig. 3. Increased strain rates cause somewhat greater strain hardening, so the use of continuous stress-strain curves yields larger values of  $m$  than the second method, which compares the flow stresses for the same structure. The second method has the advantage that several strain-rate changes can be made on one specimen, whereas continuous stress-strain curves require a specimen for each strain rate.

Strain-rate sensitivity is also temperature dependent; Fig. 4 (Ref 5) shows data for a number

of metals obtained from continuous constant strain-rate tests. Below  $T/T_M = 1/2$  ( $T/T_M$  is the ratio of testing temperature to melting point on an absolute scale), the rate sensitivity is low, but it climbs rapidly for  $T > T_M/2$ .

More detailed data for aluminum alloys are given in Fig. 5 (Ref 6). Although the definition of  $m$  in this figure is based on shear stress and strain rate, it is equivalent to the definition derived from Eq 1. For these and many other alloys, there is a minimum in  $m$  near room temperature, and, as indicated, negative  $m$  values are sometimes found.

**Alternative Description of Strain-Rate Dependence.** For steels, Eq 1 may not be the best description of the strain-rate dependence of flow stress. There is considerable evidence that the strain-rate exponent,  $m$ , decreases as the steel is strain hardened and that it is lower for high-strength steels than for weaker steels. The data of Fig. 6 (Ref 7) show that  $m$  is inversely proportional to the flow stress,  $\sigma$ . This suggests that a better description is:

$$\frac{d\sigma}{d(\ln \dot{\epsilon})} = m' \quad (\text{Eq 4})$$

or

$$\sigma = m' \ln \frac{\dot{\epsilon}}{\dot{\epsilon}_0} + C \quad (\text{Eq 5})$$

where  $m'$  is the new rate-sensitivity constant, and  $C$  is the value of  $\sigma$  at  $\dot{\epsilon} = \dot{\epsilon}_0$  ( $C$  and  $\dot{\epsilon}_0$  are not

**Table 1 Stress-strain relations based on empirical (phenomenological) and theoretical (Kocks) considerations**

The Voce and Kocks relations predict saturation.

### Phenomenological models

Holloman (parabolic)	$\sigma = K\epsilon^n$
Ludwik	$\sigma = \sigma_0 + K'\epsilon^{n'}$
Swift	$\sigma = K_2(\epsilon + \epsilon_0)^{n_2}$
Voce	$\sigma = \sigma_s - (\sigma_s - \sigma_0) \exp(-N\epsilon)$
Modified Voce (Hockett-Sherby)	$\sigma = \sigma_s - (\sigma_s - \sigma_0) \exp(-N'\epsilon^p)$

### Kocks Model

$$\theta = \theta_0 \left( 1 - \frac{\sigma}{\sigma_s} \right)$$

where  $\theta = \frac{d\sigma}{d\epsilon} \bigg|_{\epsilon, T}$

Fig. 3 Two methods of determining  $m$ . (a) Two continuous stress-strain curves at different strain rates are compared at the same strain, and  $m = \ln(\sigma_2/\sigma_1) / \ln(\dot{\epsilon}_2/\dot{\epsilon}_1)$ . (b) Abrupt strain-rate changes are made during a tension test, and  $m = (\Delta\sigma/\sigma) / \ln(\dot{\epsilon}_2/\dot{\epsilon}_1)$ .

independent constants; if  $\dot{\epsilon}_0$  is taken as unity,  $C = \sigma$  for  $\dot{\epsilon} = 1$ ).

Because  $C$  must depend on strain, Eq 5 indicates that the contributions of strain and strain rate to flow stress are additive rather than multiplicative. Another indication supporting this postulate is the observation that the strain-hardening exponent,  $n$ , for steels decreases at high strain rates (Fig. 7).

When  $C$  in Eq 5 is  $K'\epsilon^{n'}$ :

$$\sigma = m' \ln \frac{\dot{\epsilon}}{\dot{\epsilon}_0} + K' \epsilon^{n'} \quad (\text{Eq 6})$$

The usual exponent  $n$  in  $\sigma = K\epsilon^n$  can be expressed as:

$$n = \frac{\epsilon d\sigma}{\sigma d\epsilon} \quad (\text{Eq 7})$$

Then, evaluating  $n$  in terms of Eq 6:

$$n = n' / \left[ \frac{m' \ln(\dot{\epsilon}/\dot{\epsilon}_0)}{K' \epsilon^{n'}} + 1 \right] \quad (\text{Eq 8})$$

so, if  $m'$  and  $n'$  are truly constant,  $n$  would appear to decrease with strain rate.

#### Temperature Dependence of Flow Stress.

At elevated temperatures, the rate of strain hardening falls rapidly in most metals with an increase in temperature, as shown in Fig. 8 (Ref 8). The flow stress and tensile strength, measured at constant strain and strain rate, also drop with increasing temperature, as illustrated in Fig. 9. However, the drop is not always continuous; often, there is a temperature range over which the flow stress is only slightly temperature dependent or, in some cases, even increases

slightly with temperature. The temperature dependence of flow stress is closely related to its strain-rate dependence. Decreasing the strain rate has the same effect on flow stress as raising the temperature, as indicated schematically in Fig. 10. Here, it is clear that at a given temperature, the strain-rate dependence is related to the slope of the  $\sigma$  versus  $T$  curve; where  $\sigma$  increases with  $T$ ,  $m$  must be negative.

The simplest quantitative treatment of temperature dependence is that of Zener and Hollomon, who argued that plastic straining could be treated as a rate process using the Arrhenius rate law,  $\text{rate} \propto \exp(-Q/RT)$ , which has been successfully applied to many rate processes. They proposed that:

$$\dot{\epsilon} = A e^{-Q/RT} \quad (\text{Eq 9})$$

where  $Q$  is an activation energy,  $T$  the absolute temperature, and  $R$  the gas constant. Here, the constant of proportionality,  $A$ , is both stress and strain dependent. At constant strain,  $A$  is a function of stress alone [ $A = A(\sigma)$ ], so Eq 9 can be written as:

$$A(\sigma) = \dot{\epsilon} e^{Q/RT} \quad (\text{Eq 10})$$

or more simply as:

$$\sigma = f(Z) \quad (\text{Eq 11})$$

where the Zener-Hollomon parameter  $Z = \dot{\epsilon} e^{Q/RT}$ . This development predicts that if the strain rate to produce a given stress at a given temperature is plotted on a logarithmic scale against  $1/T$ , a straight line should result with a slope of  $-Q/R$ . Figure 11 shows such a plot.

**Fig. 4** Variation of the strain-rate sensitivity of different materials with homologous temperature,  $T/T_M$ . Adapted from Ref 5

**Fig. 5** Temperature dependence of the strain-rate sensitivities of 2024 and pure aluminum. Source: Ref 6

Correlations of this type are very useful in relating temperature and strain-rate effects, particularly in the high-temperature range. However, such correlations may break down if applied over too large a range of temperatures, strains, or strain rates. One reason is that the rate-controlling process, and hence  $Q$ , may change with temperature or strain. Another is connected with the original formulation of the Arrhenius rate law in which it was supposed that thermal fluctuations alone overcome an activation barrier, whereas in plastic deformation, the applied stress acts together with thermal fluctuations in overcoming the barriers, as indicated in the following development.

Consider an activation barrier for the rate-controlling process as in Fig. 12. The process may be cross slip, dislocation climb, and so on. Ignoring the details, assume that the dislocation moves from left to right. In the absence of applied stress, the activation barrier has a height  $Q$ , and the rate of overcoming this barrier would be proportional to  $\exp(-Q/RT)$ . However, unless the position at the right is more stable, that is, has a lower energy than the position on the left, the rate of overcoming the barrier from right to left would be exactly equal to that in overcoming it from left to right, so there would be no net dislocation movement. With an applied stress,  $\sigma$ , the energy on the left is raised by  $\sigma V$ , where  $V$  is a constant with dimensions of volume, and on the right the energy is lowered by  $\sigma V$ . Thus,

the rate from left to right is proportional to  $\exp[-(Q-\sigma V)/RT]$ , and from right to left the rate is proportional to  $\exp[-(Q+\sigma V)/RT]$ . The net strain rate then is:

$$\begin{aligned}\dot{\epsilon} &= C \{ \exp[-(Q-\sigma V)/RT] - \exp[-(Q+\sigma V)/RT] \} \\ &= C \exp(-Q/RT) [ \exp(\sigma V/RT) - \exp(-\sigma V/RT) ] \\ &= 2C \exp(-Q/RT) \sinh(\sigma V/RT) \quad (\text{Eq 12})\end{aligned}$$

To accommodate data better, and for some theoretical reasons, a modification of Eq 12 has been suggested (Ref 9, 10). It is:

$$\dot{\epsilon} = A [\sinh(\alpha\sigma)]^{1/m} \exp(-Q/RT) \quad (\text{Eq 13})$$

Steady-state creep data over many orders of magnitude of strain rate correlate very well with Eq 13, as shown in Fig. 13 (Ref 11).

It should be noted that if  $\alpha\sigma \ll 1$ ,  $\sinh(\alpha\sigma) \approx \alpha\sigma$ , so Eq 13 reduces to:

$$\dot{\epsilon} = A \exp(-Q/RT) \cdot (\alpha\sigma)^{1/m}$$

or

$$\begin{aligned}\sigma &= A' \dot{\epsilon}^m \exp(mQ/RT) \\ \sigma &= A' Z^m\end{aligned} \quad (\text{Eq 14})$$

which is consistent with both the Zener-Hollomon development, Eq 11, and the power-law expression, Eq 1.

Because  $\sinh(x) \rightarrow e^x/2$  for  $x \gg 1$ , at low temperatures and high stresses, Eq 13 reduces to:

$$\dot{\epsilon} = C \exp(\alpha' \sigma - Q/RT) \quad (\text{Eq 15})$$

but now strain hardening becomes important, so  $C$  and  $\alpha'$  are both strain and temperature dependent. Equation 15 reduces to:

$$\sigma = C + m' \ln \dot{\epsilon} \quad (\text{Eq 16})$$

which is consistent with Eq 5 and explains the often-observed breakdown in the power-law strain-rate dependence at low temperatures and high strain rates.

### Isothermal Constitutive Model (Ref 12)\*

The temperature dependence of the constituent processes is essential in a description of metal deformation, but it is convenient to first develop the model for a constant temperature. The grain deformation consists of elastic, microplastic, and grossly plastic (macroplastic) parts, as detailed in Fig. 14. The elastic part is assumed Hookean, and stress rate,  $\dot{\sigma}$ , is given in terms of elastic strain rate,  $\dot{\epsilon}_e$ , by:

$$\dot{\sigma} = E \dot{\epsilon}_e \quad (\text{Eq 17})$$

where  $E$  is the modulus of elasticity. This strain is instantaneously recoverable during unloading.

**Microplastic strain** involves dislocation motion over extremely short distances, such as that between obstacles. The term *microplastic* is used in a broad sense and includes anelastic strain (completely recoverable) and other microplastic components that may not be fully recoverable. Such strain can occur during the piling up of dislocations against barriers, which requires increased stress for their motion. As the stress rises, new dislocations of the appropriate sign are activated and those of the opposite sign are annihilated. Thus, the density of mobile dislocations increases during unloading without their release from the barriers. Conversely, their density is decreased due to annihilation and dislocation runback during unloading. Upon reverse reloading, there is again a rise in the dislocation density of the reverse sign. Thus,

stress depends on mobile dislocation density,  $\rho_m$ , through (Ref 13):

$$\sigma \propto \sqrt{\rho_m} \quad (\text{Eq 18})$$

where  $\rho_m$  in turn is proportional to the microplastic strain,  $\epsilon_a$ , through the relation (Ref 14):

$$\rho_m \propto \epsilon_a \quad (\text{Eq 19})$$

Combining Eq 18 and 19,  $s \propto \sqrt{\epsilon_a}$ , a convenient form being  $s = K' \epsilon_a^{0.5}$ , where  $K'$  is the microplastic strength constant, and  $s$  is the internal back stress. This kind of parabolic dependence is in agreement with the nonlinear nature of microplastic deformation commonly observed and contrasts with the choice of a single anelastic modulus that has been attempted by some investigators. To indicate the nonlinear microplastic part, the curve in Fig. 14 is extrapolated beyond the grain yield stress.

In addition to the strain dependency, there is also a velocity dependence of stress even for such small degrees of dislocation movement, and the effective stress,  $\sigma_e$ , that drives the dislocation velocity is given, following Johnston and Gilman's work (Ref 15), by:

$$\sigma_e = L \dot{\epsilon}_a^m \quad (\text{Eq 20})$$

where  $L$  is a constant,  $m$  is the strain-rate sensitivity index, and  $\sigma_e$  is given by  $\sigma - (K' \epsilon_a^{0.5})$ . Therefore, stress is given in terms of anelastic strain by:

$$\sigma = K' \epsilon_a^{0.5} + L \dot{\epsilon}_a^m \quad (\text{Eq 21})$$

Microplastic strain is essentially plastic in the sense of its origin; on unloading, however,

it is recoverable either fully or partly in a time-dependent manner, because there is no dislocation intersections and defect structure development to cause its storage. Thus, stress decreases during and after unloading, releasing  $\epsilon_a$ . Equation 21 suggests that upon rapid loading in the anelastic regime, the rate-dependent part of the stress,  $L \dot{\epsilon}_a^m$ , could initially be large. However, when stress is held constant,  $\dot{\epsilon}_a$  drops, and the strain-dependent part increases at the expense of the rate-dependent part. In addition to the dislocation-based anelasticity discussed so far, anelastic strain is also contributed by grain-boundary sliding at extremely low stresses, which is excluded from the present model.

**Plastic.** As the mobile dislocation density builds up to a significant level, leakage occurs through the barriers, aided by thermal activation. Consequently, yielding begins, starting with the grains most favorably aligned to the applied stress direction (highest critical resolved shear stress). This occurs as  $\sigma$  (given by Eq 21) exceeds the grain yield stress,  $y$ . The deformation is truly plastic (nonreversible), because dislocations start intersecting and defect structure begins to become stored. Total dislocation density increases and leads to strain hardening, that is, greater internal back stress (or glide resistance) has to be overcome in order to keep dislocations moving at the desired rate.

Strain rate is, again, related to the effective stress through its dependence on dislocation velocity, as in the Gilman-Johnston relationship. Thus, the grain contribution to the plastic strain rate is given by:

$$\dot{\epsilon}_g \propto (\sigma - g)^p \quad (\text{Eq 22})$$

**Fig. 9** Decrease of tensile strength of pure copper, silver, and aluminum with homologous temperature. Source: Ref 8

**Fig. 10** Schematic plot showing the temperature dependence of flow stress for some alloys. In the temperature region where flow stress increases with temperature, the strain-rate sensitivity is negative.

where  $p$  is a constant exponent, and  $g$  is the internal strength due to defect structure, which equals the values of back stress,  $s$ , during monotonic loading in the plastic range. From Eq 22, the applied stress can be written as:

$$\sigma = g + L\dot{\epsilon}_g^m \quad (\text{Eq 23})$$

where  $L$  is the proportionality constant in Eq 22, and  $m (= 1/p)$  is the strain-rate sensitivity index.

Internal strength is a function of the current defect structure and is determined by the net storage of dislocations that occurs through the simultaneous operation of work hardening (dislocation multiplication, tangle formation, etc.) and thermally assisted recovery processes (annihilation, rearrangement, etc.) (Fig. 15). Thus,  $g$  is a scalar quantity unlike applied stress, internal stress, or strain rate, which can change sign. While  $g$  can decrease as a result of recovery during unloading or relaxation, the maximum value of  $g$  remains fixed as  $g^*$  and represents the strength state of the material. Further plastic deformation is possible only if  $g \geq g^*$  (the equality indicates a steady state). During plastic deformation, as  $g$  increases, microplastic strain also increases, because  $|s|$  must maintain equilibrium with  $g$ .

The functional form for the strain-hardening part alone for polycrystalline aggregates is not adequately known, because measured stress-strain curves already contain elements of recovery. However, multiple slip is known to start at relatively low strains in polycrystals. For single crystals, this corresponds to stage II hardening, which is approximated by a linear behavior. The accuracy of the linearity may, however, be argued in many instances. In fact, the change of curvature from stage I to stage III

invariably imposes a linear region, thereby questioning the existence of a real linear hardening regime.

The parabolic nature of polycrystalline hardening curves is often attributed to the action of cross slip, which continuously reduces the hardening rate. Although this is frequently referred to as dynamic recovery and is aided by thermal fluctuation, it is distinctly different from a thermally assisted, time-dependent rearrangement of dislocations (considered in the next section). Because cross slip is stress assisted as well as time dependent, even during infinitely fast tests cross slip would occur as the stress rises above that required to overcome the Cottrell-Lomar barriers. Because more of these barriers are present at higher levels of internal stress, cross slip at higher stresses would release greater bursts of strain and would lead to a hardening rate decaying with stress. Thus, while there is an additional time dependency of cross slip, the stress dependency alone can be responsible for the nonlinear hardening rate (concave toward the strain axis) in metals. Polycrystals have an additional requirement of grain rotation during deformation, which changes the slip direction orientation and is likely to cause a further departure from linear hardening rate. Thus, it seems reasonable to represent the strain-hardening component by an equation of the form:

$$g = K\epsilon_g^n \quad (\text{Eq 24})$$

where  $K$  is the strength constant, and  $n$ , the strain-hardening exponent, varies between 0 and 1 and thus can include both linear and parabolic hardening behaviors (Fig. 15). Both  $K$  and  $n$  may be functions of temperature. Again, the exact functional form of the strain-hardening equation

**Fig. 11** Strain-rate and temperature combination for various levels of flow stress. Source: Ref 6

is not emphasized here but is left to be determined experimentally; this simple form is chosen only for analytic convenience. Because the internal strength also depends on recovery effects, the proper form for expressing strain-hardening effects is through the differential of Eq 24 and only in terms of the state parameter,  $g$ , as follows:

$$\partial g / \partial \epsilon_g = nK^{1/n} / g^{1/n-1} \quad (\text{Eq 25})$$

In addition to the parabolic nature of the strain-hardening part, one reason why experimental stress-strain curves are significantly concave toward the strain axis is the simultaneous operation of the time-dependent thermal recovery process, which reduces internal stress by annihilation of loose dislocations and rearranging them in stabler networks and cell walls. This can occur by cross slip, climb, and similar processes. Further recovery can occur by coarsening of the dislocation network structure. The rate of recovery has been shown to be strongly dependent on the dislocation density (Ref 16), which in turn determines the internal strength. In general, the recovery process cannot reduce the internal strength to the original yield strength,  $y$ . The residual stress after very long times of recovery,  $x$ , is usually greater than  $y$  and is dependent on the value of the internal strength experienced by the material prior to start of a long-time recovery (Ref 16, 17). Thus, the time rate of recovery,  $\partial g/\partial t$ , is assumed to be proportional to the recoverable part of the internal strength ( $g-x$ ). In fact, Friedel's network coarsening model (Ref 18) suggests:

$$-\partial g/\partial t = \alpha_d(g-x)^r \quad (\text{Eq 26})$$

where the exponent  $r \sim 3$ . The rate constant for dynamic recovery,  $\alpha_d$ , needs to be determined experimentally. The value of  $x$  is assumed to be given by:

$$g^* - x = f(g^* - y) \quad (\text{Eq 27})$$

where  $f$  is the recoverable fraction, and  $g^*$  is the internal strength to which the material was raised prior to recovery. During monotonic loading,  $g^* = g = \text{sl}$ , whereas during unloading or load relaxation,  $g^* \geq g$ . Substituting  $g$  in place of  $g^*$  in Eq 27 for monotonic loading, recovery rate in Eq 26 is given by:

$$-\partial g/\partial t = \alpha_d[f(g-y)]^r \quad (\text{Eq 28})$$

More is said later about recovery during unloading and load relaxation tests.

In resemblance to the Bailey-Orowan model (Ref 19, 20), the deformation resistance of the stored dislocation structure is given by the incremental integration of strain-hardening and dynamic recovery components. Thus, the rate of increment in internal stress,  $\dot{g} = (\partial g/\partial \epsilon_g)\dot{\epsilon}_g + (\partial g/\partial t)_{\text{recov}}$ , is given by combining Eq 25 and 28 as:

$$\dot{g} = (nK^{1/n}/g^{1/n-1})\dot{\epsilon}_g - \alpha_d[f(g-y)]^r \quad (\text{Eq 29})$$

Fig. 12 Schematic illustration of an activation barrier for slip and the effect of applied stress on skewing the barrier

This, however, is quite different from Bailey-Orowan's formulation in that the constituent terms are now dependent on internal stress. Furthermore, the hardening Eq 25 is temperature dependent and is not simply the same as that at absolute zero. The change in it is caused by an increase in stress-dependent cross slip as well as a decrease in shear modulus with increasing temperature. The value of internal strength can be obtained by integrating Eq 29 over time and then combining that with Eq 23 to obtain the flow stress.

**Unloading and Reverse Loading.** The unloading curve from a stress of  $\sigma^*$  is shown diagrammatically in Fig. 16. As stress drops from  $\sigma^*$  to  $g^*$  (internal strength corresponding to  $\sigma^*$ ), it actually accompanies a small forward plastic strain component; this is why the slope of the unloading curve in this region is steeper than elastic slope. Below  $g^*$ , all forward plastic strain stops, and reverse anelastic strain from dislocation runback starts. Thus, below the point  $g^*$ , an equation similar to Eq 21 is valid for the reverse anelastic strain. A general equation for this that incorporates the direction of stress and strain is given by:

$$\sigma - g^* \text{sgn}(\sigma^*) = [K'|\epsilon_a|^{0.5} + L|\dot{\epsilon}_a|^m] \text{sgn}(\dot{\epsilon}_a) \quad (\text{Eq 30})$$

where reverse  $\epsilon_a$  is measured from the point  $g^*$  on the diagram. When zero stress is attained,  $\epsilon_e$  becomes zero; however, reverse  $\dot{\epsilon}_a$  cannot become zero instantaneously but decreases slowly as the reverse  $\epsilon_a$  increases, thereby maintaining zero stress. After very long times, all of the forward anelastic strain is recovered. This recovery of microplastic strain is known as elastic aftereffect.

If no recovery of internal strength occurs during unloading and reverse loading, reverse plastic flow would begin at a stress of  $-g^*$ , as shown in Fig. 16. Once  $-g^*$  is reached, internal and applied stress curves are essentially the continuations of the forward loading curves, with reverse sign for stress and strain. However, because this is preceded by a fairly large amount of anelastic strain (corresponding nearly to a stress change of  $2g^*$ ), both internal and applied stress curves in the plastic regime are below the corresponding curves had there been no reverse anelastic strain. Thus, Bauschinger effect is incorporated into the model through microplastic strain. In precipitation-hardening materials, the dislocation loops formed around precipitates provide a larger number of dislocations of the

opposite sign during reverse loading. The effect can be thought to produce either a lower microplastic strength constant,  $K'$ , or a reduced  $g$  (for reverse flow), leading to an enhanced Bauschinger effect. Which one of these two possibilities is more plausible needs to be determined from experimental data.

Furthermore, when there is thermal recovery or internal strength during unloading and reverse loading, reverse flow begins at a stress whose absolute magnitude is less than  $g^*$ . A more pronounced Bauschinger effect results from this.

Fig. 13 Plot of Zener-Hollomon parameter versus flow-stress data for aluminum showing the validity of the hyperbolic sine relationship, Eq 13. Source: Ref 11

**Fig. 14** Schematic stress-strain diagram illustrating elastic ( $\epsilon_e$ ), microplastic ( $\epsilon_a$ ), and macroplastic ( $\epsilon_g$ ) strains. Note that in the macroplastic range,  $\epsilon_a$  is associated with internal back stress ( $s$ ), while  $\epsilon_g$  is associated with effective stress.

**Fig. 15** Internal strength is the sum of the net increments from strain hardening and dynamic recovery components. The rate of the former is obtained from the basic hardening curve (same for the same level of  $g$ ) and decreases with increasing  $g$ , while that of the latter increases. The basic hardening curve is a function of temperature and not the one for absolute zero.

It should be pointed out that Eq 30 is a simplistic form for monotonic loading within the microplastic region, with no change in the direction of strain rate. A differential form is preferred, however, for internal stress under arbitrary strain-rate history. This is given by:

$$\dot{s} = \left( \frac{0.5K'^2}{s-s^*} \right) \dot{\epsilon}_a \quad (\text{Eq 31})$$

A comparison between constant load and constant stress results on steady-state creep rate versus stress may be made from the following considerations: If  $\dot{\epsilon}_b$  is ignored for the moment, minimum or steady-state strain rate corresponds to  $\dot{\epsilon}_g = 0$ . It can be shown by considering  $g = g_0$  that for minimum creep rate (steady state):

$$\dot{\sigma} = \dot{g} \quad (\text{Eq 32})$$

For a constant stress test ( $\dot{\sigma} = 0$ ), Eq 32 with the help of Eq 29 leads to:

$$\dot{\epsilon}_s = \frac{\alpha_d [f(g-y)]^r}{nK^{1/n} / g^{1/n-1}} \quad (\text{Eq 33})$$

where  $\dot{\epsilon}_s$  is the steady-state  $\dot{\epsilon}_g$ . If  $y \ll s$ ,  $\dot{\epsilon}_s$  may further be simplified into the expression:

$$\dot{\epsilon}_s = A' g^{(1/n+r-1)} = A' (\sigma - L \dot{\epsilon}_s^m)^{(1/n+r-1)} \quad (\text{Eq 34})$$

where  $A' = [\alpha_d f^r / nK^{1/n}]$ . Rearranging, stress can be expressed as:

$$\sigma = A \dot{\epsilon}_s^M + L \dot{\epsilon}_s^m \quad (\text{Eq 35})$$

**Fig. 16** Schematic loading and reverse loading diagram in the plastic range

where  $A = 1/A'$  and  $M = (1/n+r-1)^{-1}$ . At low temperatures,  $A$  is very large, and the hardening behavior predominantly determines flow stress. The value of  $M$  at low temperature is difficult to determine experimentally, because steady state occurs at extremely large

strains for which the measurements of stress in a monotonic uniaxial test is complicated by necking, fracture, or barreling. The instantaneous rate sensitivity resulting from the effective stress may be determined by the step strain-rate test and is usually found to be small

Fig. 17 Minimum creep rate versus stress curves for two different effective stress levels, showing the importance of its exponent,  $m$ , in comparison to that of the internal stress,  $M$

at low temperature, because both  $L$  and  $m$  are small.

As temperature is raised,  $A$  decreases while  $L$  and  $m$  increase. The value of  $m$  can approach 0.3, and when  $A$  is small, the effective stress may become the dominant term (as in class I alloys). Conversely, when  $A$  still remains large, the creep exponent may be approximately 5 (or more), that is,  $M = 0.2$  or less, as in the case of class II alloys or pure metals. In the case of diffusional creep, which has not been modeled here,  $M$  could approach the value of 1.

Thus, depending on whether the first term (saturated internal strength) or the second term (effective stress) on the right side of Eq 35 is dominant,  $\sigma$  versus  $\dot{\epsilon}_s$  data can exhibit either a rate-sensitivity index of  $M$  or  $m$  or somewhere in between (creep exponent is inverse of this index). This is shown in Fig. 17, where constant stress test yields a nearly linear behavior (at least in a double-logarithmic scale), even though no attempt has been made to simulate the absolute positions of the curves for any particular

material. The low rate portions of the relaxation curves can be nearly superimposed by translation along a slope of  $M$ . Thus, while the low strain-rate behavior is governed by the rate sensitivity of internal strength, the higher rate behavior is controlled by that of effective stress, with an intermediate behavior persisting in between. For creep at low strain rates (or stress), the influence of grain yield stress ( $y$ ) becomes important as the curves in Fig. 17 bend toward a lower rate sensitivity (or higher stress exponent). At low enough strain rates, a higher rate sensitivity may again develop because of the dominance of grain-boundary processes ( $\dot{\epsilon}_b$ ), depending on the relative magnitudes of  $\sigma_0$  and  $y$ .

If load is maintained constant instead of stress,  $\dot{\sigma}$  is no longer 0 but equal to  $\sigma \dot{\epsilon}_t$ . Again because  $\dot{\epsilon}_g = 0$ ,  $\dot{g} = \sigma \dot{\epsilon}_t$ . Thus, in place of Eq 33 and 34, one obtains:

$$\dot{\epsilon}_s = \frac{\alpha_d [f(g-y)]^r}{nK^{1/n} / g^{1/n-1} - \sigma} \quad (\text{Eq 36})$$

This equation can be solved for  $\dot{\epsilon}_s$  for given values of  $\sigma$  and the constants.

## Dynamic Recovery (Ref 21)\*

**Mechanisms for Dynamic Recovery.** Very few efforts have been reported pertaining to the operative mechanisms during restoration via dynamic recovery at hot-working strain rates. However, it is a reasonable assumption that the basic softening events, characterizing constant-rate testing at low and intermediate temperatures and also creep, are relevant even under the conditions of hot deformation.

Mecking and Lücke (Ref 22, 23) introduced a formal description of the superposition of

\*Adapted from: William Roberts, "Dynamic Changes That Occur during Hot Working and Their Significance Regarding Microstructural Development and Hot Workability," in *Deformation, Processing, and Structure*, G. Krauss, Ed., American Society for Metals, 1984, p 109-184

hardening and softening during plastic flow, where it is assumed that the individual contributions of these two processes to stress and strain are additive, that is:

$$d\epsilon = d\epsilon_h + d\epsilon_{sf}; \quad d\sigma = d\sigma_h - d\sigma_{sf} \quad (\text{Eq 37})$$

In terms of the work-hardening rate,  $\theta$ ,

$$\theta = \theta_{II} - \frac{1}{\dot{\epsilon}} (\theta_{II} \dot{\epsilon}_{sf} + \dot{\sigma}_{sf}) \quad (\text{Eq 38})$$

where  $\theta_{II}$  is a constant athermal hardening rate equivalent to that in stage II single-crystal hardening; even at high temperatures, it is presumed that  $\theta$  approaches  $\theta_{II}$  asymptotically at small strains. If the softening (dynamic recovery) processes are considered as single dislocation events with frequency  $\dot{N}$ , then both  $\dot{\epsilon}_{sf}$  and  $\dot{\sigma}_{sf}$  are proportional to  $\dot{N}$ , and Eq 38 is replaced by:

$$\theta = \theta_{II} - q \left( \frac{\dot{N}}{\dot{\epsilon}} \right) \quad (\text{Eq 39})$$

where the proportionality constant  $q$  is related to the strain increase and stress decrease associated with a single softening event. Equation 39 should be compared with that derivable from the assumptions of the Bailey-Orowan (Ref 19, 20) theory of creep, in which the unit softening events are considered to be activated by thermal vibrations only, that is, exactly as for static recovery. On this basis,  $\dot{N}$  is constant, and Eq 39 can be modified ( $\dot{N}$  proportional to  $r$  = rate of recovery) to yield:

$$\theta = \theta_{II} - \frac{r}{\dot{\epsilon}} \quad (\text{Eq 40})$$

In the steady-state limit,  $\theta = 0$ , and  $\dot{\epsilon}_s = r/\theta_{II}$ , which is the Bailey-Orowan relation for recovery-controlled creep. By applying Eq 48, one can write for  $r$  during creep at low stresses:

$$r = r_0 \sigma^n \exp(-Q/RT) \quad (\text{Eq 41})$$

where  $r_0 = B\theta_{II}$  ( $\theta_{II}$  independent of  $T$ ,  $\dot{\epsilon}$  except via the temperature dependence of the shear modulus). However, because Eq 40 should also apply to the situation away from the steady state, then this relationship together with Eq 41 predicts that the work-hardening rate will exhibit a strong dependence on both stress and strain rate that is much more pronounced than the experimental evidence would indicate.

The physical basis of the Bailey-Orowan approach has been disputed in a number of papers (Ref 2, 24–27). The crux of the problem lies in the assumption that, at a given dislocation structure, the time frequency of recovery events is constant, and that each event only contributes to an elementary reduction in stress but not to a corresponding increase in strain. It would appear that this presumption is questionable. In terms of the formalism given by Mecking and Lücke (Ref 22, 23), the proportionality constant,  $q$ , can contain terms due to both the elementary stress decrease and the elementary strain increase from a single softening event, that is:

$$q = \theta_{II} \cdot d\epsilon_{el} + d\sigma_{el}$$

Hence,  $\dot{N}$  in Eq 39 can depend on the current level of applied stress or strain rate, that is, the restoration takes place via thermally assisted strain softening rather than the time-dependent, static-type recovery of the Bailey-Orowan approach and, as such, is dynamic recovery in its true sense. The interdependence of strain rate and stress at a given structure makes it difficult to decide, from experimental information, whether the stress level (the driving force) or the strain rate (the motion of dislocations) is the quantity that determines the frequency of softening events. Mecking and Lücke (Ref 22, 23) considered the  $\sigma(\epsilon)$  behavior in terms of a spectrum of softening centers, each with its specific activation stress. The number of active centers then increases with increasing degree of hardening, and the  $\sigma(\epsilon)$  curve flattens continuously. Assistance from thermal vibrations causes the work-hardening rate at a given strain to decrease with increasing temperature and decreasing strain rate. An alternative approach, in which the softening events are considered to be triggered by moving dislocations, has been presented by Kocks (Ref 2).

In the detailed models for dislocation creep presented by Öström and Lagneborg (Ref 28, 29), the dynamic recovery mechanism presumed to operate is one proposed originally by Freidel (Ref 18). He considered the mesh growth of a Frank network (which may exist uniformly throughout the crystal or locally in subgrain walls) via diffusion-controlled climb. The rate of growth of the average link size ( $\bar{l}$ ) is:

$$\frac{d\bar{l}}{dt} = \frac{M\tau}{\bar{l}} \quad (\text{Eq 42})$$

where  $M$  is a mobility that, for diffusion-controlled climb, is related to the self-diffusion coefficient. For growth of an individual link of size  $l$ , Öström and Lagneborg (Ref 28) draw an analogy with grain growth and propose the expression:

$$\frac{dl}{dt} = M\tau \left( \frac{1}{l_{cr}} - \frac{1}{l} \right) \quad (\text{Eq 43})$$

where  $l_{cr}$  is a critical value above which links increase in size and below which they shrink. In a simple treatment, the dislocation density is functionally related to  $\bar{l}$ , that is,  $\rho = \bar{l}^{-2}$ , and the rate of decrease of dislocation density due to recovery is then easily obtained via integration of Eq 42:

$$\left. \frac{d\rho}{dt} \right|_{rec} = -2M\tau\rho^2 \quad (\text{Eq 44})$$

Öström and Lagneborg (Ref 28, 29) have adopted a more advanced formulation based on Eq 43, because in their model they consider a distribution of link sizes that is continuously modified via the accumulation of links due to glide/storage and their disappearance through shrinkage of the smallest meshes and participation in glide (largest links for which  $l > \alpha' \mu b/\sigma$ ). In its most refined form (Ref 29), the model

offers a satisfactory description of the primary and secondary stages of creep in austenitic stainless steels. The steady-state dislocation density and its stress dependence are determined principally by  $l^* = 2\mu b/\sigma$ . In this sense, the simple argument culminating in Eq 44 and the more advanced theory lead to similar results.

Öström and Lagneborg's treatment has been criticized by Kocks and Mecking (Ref 26) on a number of points, the principal one being that the Friedel theory, for the growth of meshes in a Frank network, is essentially a model of time-dependent static recovery. However, in a more recent paper (Ref 27), these latter authors have attempted to develop a unified treatment of static (i.e., time dependent) and dynamic recovery. In this treatment, the problem associated with the simple Bailey-Orowan formalism for recovery creep, that is, that the wrong dependence of the work-hardening rate on stress and strain rate is predicted (Eq 40 and 41), is avoided because the recovery rate,  $r$ , is not controlled by a constant activation energy but rather by one that depends on the local forward internal stress experienced by dislocation segments in tangles. The substance of this model is a distribution of forward internal stresses on dislocation segments. Above a critical forward stress,  $\sigma_s$ , the athermal storage rate (defined by  $\theta_{II}$ ) is balanced by recovery; the rate of recovery under these conditions may then be written as:

$$\left. -\frac{df}{dt} \right|_{rec} = f(\sigma_s) v_0 \exp \left\{ -\frac{\Delta G(\sigma_s/\sigma_m)}{RT} \right\} \quad (\text{Eq 45})$$

where  $f$  is the distribution function for forward stresses, and  $\sigma_m$  is the mechanical collapse stress at which dislocations would break free of the tangles even in the absence of thermal activation. On this basis, the net change in dislocation density for applied stress levels below  $\sigma_s$  ( $\equiv$  steady-stage stress) is:

$$\frac{d\rho}{d\epsilon} = h(\sigma, \sigma_s)(\sigma_s - \sigma) \quad (\text{Eq 46})$$

This applies because, above  $\sigma_s$ ,  $df/d\epsilon = 0$ . The function  $h$  depends on the average segment length being stored,  $\bar{l}$ , and on  $df/d\epsilon$ . Kocks and Mecking argue that  $h \propto \sigma/\sigma_s$  and so, assuming a proportionality between  $\sigma$  and  $\sqrt{\rho}$ :

$$\frac{d\sigma}{d\epsilon} = \text{const.} (1 - \sigma/\sigma_s) \quad (\text{Eq 47})$$

which is the formalism for the  $\sigma(\epsilon)$  curve proposed originally by Voce (Ref 30). Equation 47 is characterized by a weak dependence of  $d\sigma/d\epsilon$  on  $\sigma$  and  $\dot{\epsilon}$  (through that of  $\sigma_s$ ) and is thus consistent with experimental observations pertaining to the dependence both of the strain-hardening rate prior to  $\sigma_s$  and of the steady-state stress on  $\dot{\epsilon}$ . However, the authors point out that this model, which involves only time-dependent recovery, will be invalidated if stress- or strain-rate-activated recovery events are rate controlling.

**Steady-State Stress.** In general, creep and high-temperature deformation at a given rate should, under equivalent conditions, lead to the same value for  $\sigma_s$ ; this has been confirmed for pure aluminum by Mecking and Gottstein (Ref 31). However, such a situation is not likely to hold in a comparison of constant-rate tests under hot-working conditions and creep, which are often characterized by different activation energies. Based on the so-called temperature-compensated strain rate, as originally proposed by Zener and Hollomon, where  $\sigma = f(\dot{\epsilon} \exp(Q/RT)) = f(Z)$ , the temperature and strain-rate dependence of  $\sigma_s$  is defined by the following equations:

$$Z = B(\sigma^n) \quad (\text{Eq 48})$$

or

$$Z = B' \exp(\beta \sigma) \quad (\text{Eq 49})$$

or if such simplification is not always possible, in the unified form:

$$Z = B'' [\sinh(\alpha \sigma)]^n \quad (\text{Eq 50})$$

Kocks (Ref 2) has proposed that, at low temperatures,  $n$  in Eq 48 can be identified with  $\zeta/kT$ , where  $\zeta$  is a constant for a given material (face-centered cubic, or fcc) and  $k$  is Boltzmann's constant; the former can be derived from a so-called  $\tau_{III}$  analysis of single-crystal stress-strain curves.

Kocks (Ref 2) presented a treatment for  $\sigma(\epsilon)$  in which recovery events are considered to be controlled by strain rate (moving dislocations). This argument leads to a formula:

$$\theta = \theta_0(1 - \sigma/\sigma_s) \quad (\text{Eq 51})$$

where  $\theta_0$  is an athermal hardening rate to which all  $\sigma(\epsilon)$  curves are asymptotic at low strains (related to, but not necessarily equal to,  $\theta_{II}$ ). Apart from minor deviations at small strains, Eq 51 was found to describe accurately the stress dependence of the work-hardening rate during the tensile testing of aluminum, copper, and an austenitic stainless steel (all polycrystalline). Because necking intervened before a steady state could be established,  $\sigma_s$  was evaluated via the extrapolation of  $\theta - \sigma$  plots to  $\theta = 0$ .

Equation 51 is rationalized by Kocks in terms of dislocation storage at a rate, with respect to strain, that is proportional to  $\sqrt{\rho}$ ; in fact:

$$\left. \frac{d\rho}{d\epsilon} \right|_{\text{stor}} = \frac{k_1 \sqrt{\rho}}{b}$$

where  $k_1$  is a proportionality constant between mean-free path and  $\sqrt{\rho}$ . In evaluating  $(d\rho/d\epsilon)_{\text{rec}}$ , it is assumed that the probability of a recovery event is proportional to the number of times a potential recovery site is contacted by a moving dislocation. If a length of dislocation  $l_r$  is annihilated per recovery event, then for a unit area of

slip plane  $dl_{\text{rec}} = l_r \rho$ , because the number of potential recovery sites is  $\rho$ . The shear-strain increment for unit area of slip plane is  $b$ , and so:

$$\frac{d\rho}{d\epsilon} = \left. \frac{d\rho}{d\epsilon} \right|_{\text{stor}} - \left. \frac{d\rho}{d\epsilon} \right|_{\text{rec}} = \frac{1}{b} (k_1 \sqrt{\rho} - k_2 l_r \rho)$$

which, in terms of hardening rates, becomes:

$$\theta = \frac{d\sigma}{d\epsilon} = \frac{\alpha \mu k_1}{2} - \frac{k_2 l_r}{2b} \cdot \sigma \quad (\text{Eq 52})$$

This expression is equivalent to Eq 51. Kocks and Mecking (Ref 27) have also derived the Voce law from fundamental arguments using a time-dependent (i.e., static) model for recovery.

In order to check whether Eq 51 applies all the way up to  $\sigma_s$ , and thereby to examine the validity of the extrapolations made by Kocks on the basis of his tensile data,  $\sigma(\epsilon)$  was determined for polycrystalline superpure aluminum (200  $\mu\text{m}$  grain size) using compression testing between 450 and 600 K and at  $\dot{\epsilon} = 0.01$  and  $1 \text{ s}^{-1}$ . Lubrication with polytetrafluoroethylene permitted friction-free compression up to a true strain of 1, which is sufficient to attain steady state for all the conditions examined. Over the relevant strain range, the compressive  $\sigma(\epsilon)$  curves are in excellent agreement with the corresponding tensile data reported by Kocks (Ref 2).

Figure 18 shows typical  $\theta - \sigma$  ( $\theta \equiv d\sigma/d\epsilon$ ) plots derived from the  $\sigma(\epsilon)$  curves for aluminum. These conform accurately to Eq 51 at low stresses, but a systematic deviation from this law is found as  $\sigma_s$  is approached. Extrapolation of the low-stress behavior will clearly lead to an underestimation of  $\sigma_s$ . For testing at 500 and 600 K and at  $0.01 \text{ s}^{-1}$ , an extrapolation after the fashion of that performed by Kocks gives  $\sigma_s = 23$  and  $15 \text{ MPa}$ , respectively; the corresponding values reported by Kocks for  $\dot{\epsilon} = 1.6 \times 10^{-2} \text{ s}^{-1}$  are 23 and  $14 \text{ MPa}$ . However, the correct, experimentally determined levels of  $\sigma_s$  are 34.5 and  $16 \text{ MPa}$ .

A careful examination of the  $\theta$  values suggests that, with the exception of small strains (less than 0.05),  $\theta$  is linearly related to  $1/\sigma$ . Some minor deviations from the law are found, especially as  $\sigma_s$  is approached, but the overall conformity must be regarded as acceptable. The slope of the  $1/\sigma$ -versus- $\theta$  plot increases systematically with increasing temperature and decreasing strain rate, or, more specifically, as  $1/\sigma_s$ . Data are reasonably well described by a straight line, which passes through the origin. Accordingly, the observed  $\sigma(\epsilon)$  behavior does not conform to Eq 51 but rather follows the law:

$$\theta = P \left( \frac{\sigma_s}{\sigma} - 1 \right) \quad (\text{Eq 53})$$

where  $P$  is the slope of  $1/\sigma_s$  versus  $d(1/\sigma)/d\theta$  (116  $\text{MPa}$ ) and is very close to being constant for the range of temperatures and strain rates investigated.

Phenomenologically, Eq 53 is easily shown to be concomitant with the following relationship for the rate of increase of dislocation density with strain:

$$\frac{d\rho}{d\epsilon} = k_1 - k_2 \sqrt{\rho} \quad (\text{Eq 54})$$

that is, dislocation accumulation at a constant rate, which is realistic if a cell or subgrain structure is established early in the deformation process, combined with dynamic recovery at a rate proportional to  $\sqrt{\rho}$ . The  $\sigma(\epsilon)$  law derived from Eq 53 is:

$$\sigma_s \ln \left( \frac{\sigma_s}{\sigma_s - \sigma} \right) - \sigma = P\epsilon \quad (\text{Eq 55})$$

The constants in Eq 54 are given by:

$$\frac{k_1}{k_2} = \frac{\sigma_s}{\alpha' \mu b}; \quad k_2 = \frac{2P}{\alpha' \mu b} \quad (\text{Eq 56})$$

Examples illustrating the degree of accord between Eq 55 and the experimentally determined  $\sigma(\epsilon)$  behavior are given in Fig. 19. In a more accurate appraisal, it is necessary to take into account the temperature dependence of elastic modulus in the evaluation of  $P$ . The general measure of agreement between the two-parameter formalism (Eq 55) and the experimental  $\sigma(\epsilon)$  is quite good but hardly perfect, especially at low strains. This reflects the inability of Eq 53 to describe the behavior under these circumstances; such is not to be expected either, in view of the fact that some initial strain is required before the equilibrium cell size (defining a constant rate of dislocation storage) is established. However, Eq 55 represents the best two-parameter description of

**Fig. 18** Plot of work-hardening rate versus flow stress for superpure aluminum, illustrating the type of extrapolation performed by Kocks (Ref 2) on his tensile data

$\sigma(\epsilon)$  under the range of experimental conditions studied.

From Eq 56:

$$k_1 = \frac{2P\sigma_s}{(\alpha'\mu b)^2} = \frac{1}{\omega b d_{\text{sub}}} \quad (\text{Eq 57})$$

where  $\omega$  is a factor for converting from shear to normal quantities. Because  $P$  is virtually independent of  $T$  and  $\dot{\epsilon}$ , then  $\sigma_s$  should be proportional to the inverse of subgrain size, which is approximately the situation found experimentally. In actual fact, the predicted exponent for  $d_{\text{sub}}$  must deviate somewhat from  $-1$  because of the temperature dependence of  $\mu$  (assuming, of course, that  $\sigma_s$  and the subgrain size are varied via changes in test temperature). Turning to the recovery term, it is clear that the proportionality constant,  $k_2$ , is approximately

independent of  $T$  and  $\dot{\epsilon}$  (Eq 56); taking  $\mu(500 \text{ K}) = 2.24 \times 10^4 \text{ MPa}$ ,  $\alpha' \doteq 1$ , and  $b = 0.286 \text{ nm}$ , then  $k_2 \doteq 4 \times 10^7 \text{ m}^{-1}$ . Following Kocks (Ref 2), it is assumed that recovery events are triggered by mobile dislocations; on this basis, the rate of decrease of  $\rho$  with respect to strain (see previous text) is:

$$\left. \frac{d\rho}{d\epsilon} \right|_{\text{rec}} = \text{const.} \frac{l_r \rho}{b}$$

where  $l_r$  is the length of dislocation lost per recovery event. The constant in the previous expression can be identified with  $\omega \cdot g$ ,  $g$  being the fraction of encounters between mobile and stationary dislocations that leads to recovery events. Kocks takes  $l_r$  to be fixed and independent of total dislocation density. However, because the unit recovery process is likely to involve indi-

vidual dislocation links, then  $l_r$  can be expected to decrease as  $\rho$  increases. For both a uniformly distributed network and a subgrain structure, one can thus anticipate that  $l_r$  is proportional to  $1/\sqrt{\rho}$  and that:

$$\left. \frac{d\rho}{d\epsilon} \right|_{\text{rec}} = \text{const.} \frac{\sqrt{\rho}}{b} \quad (\text{Eq 58})$$

in agreement with the formalism derived from experimental observations (Eq 54). Making the rough approximation that  $l_r = 1/\sqrt{\rho}$ , one has  $k_2 = \omega g/b$ , and so, with the previous value of  $k_2$  plus  $\omega = 3.1$  (fcc polycrystals),  $g$  works out to be  $4 \times 10^{-3}$ , that is, approximately one encounter in 200 results in a recovery event.

The two-parameter description of  $\sigma(\epsilon)$  embodied in Eq 55 is a very attractive one. Within the range of temperatures and strain rates investigated, the stress-strain behavior up to  $\epsilon = 1$  can be described quite accurately in terms of a material constant,  $P$ , and the steady-state stress. Furthermore, the experimental data for aluminum indicate that  $\sigma_s(\dot{\epsilon}, T)$  conforms well with  $Q = 130 \text{ kJ} \cdot \text{mol}^{-1}$ , which is very close to  $Q_{\text{SD}}$  ( $138 \text{ kJ} \cdot \text{mol}^{-1}$ ). Hence, the description of  $\sigma(\epsilon, \dot{\epsilon}, T)$  is simplified further because  $\sigma_s$  can be evaluated for any temperature and strain rate if  $Q$  is known. The entire formalism is thus based on just two quantities, which are, at least to a first approximation, independent of temperature or strain rate.

It is of interest to investigate whether or not Eq 55 can be applied to a typical commercial material, characterized by restoration during hot deformation via dynamic recovery alone. Figure 20 shows  $\sigma(\epsilon)$  curves for a ferritic stainless steel (19Cr-0.6Ti) tested in compression at temperatures between 750 and 1150 °C (1380 and 2100 °F) and at  $\dot{\epsilon} = 1 \text{ s}^{-1}$ . The agreement between the experimental points and the theoretical curves is acceptable. However, in this case,  $P$  is not constant but decreases systematically with increasing temperature. The probable explanation lies in the existence of a strain-independent flow-stress component in this commercial steel, that is, a friction stress,  $\sigma_0$ . This being the case, Eq 53 must be changed to:

$$\theta = P \left( \frac{\sigma_s - \sigma}{\sigma - \sigma_0} \right) \quad (\text{Eq 59})$$

and Eq 55 must be changed to:

$$\sigma_0 - \sigma + (\sigma_s - \sigma_0) \ln \left( \frac{\sigma_s - \sigma_0}{\sigma_s - \sigma} \right) = P\epsilon \quad (\text{Eq 60})$$

It is readily shown that the application of Eq 53 and 55 to  $\sigma(\epsilon)$  behavior characterized by a non-zero  $\sigma_0$  will result in a  $P$  value that increases with increasing  $\sigma_0$ . Hence, the data for  $P$  listed in Fig. 20 are consistent with a diminishing  $\sigma_0$  as the temperature is raised, which seems plausible. For a more accurate correlation with  $\sigma(\epsilon)$  from commercial materials, Eq 59 and 60 should

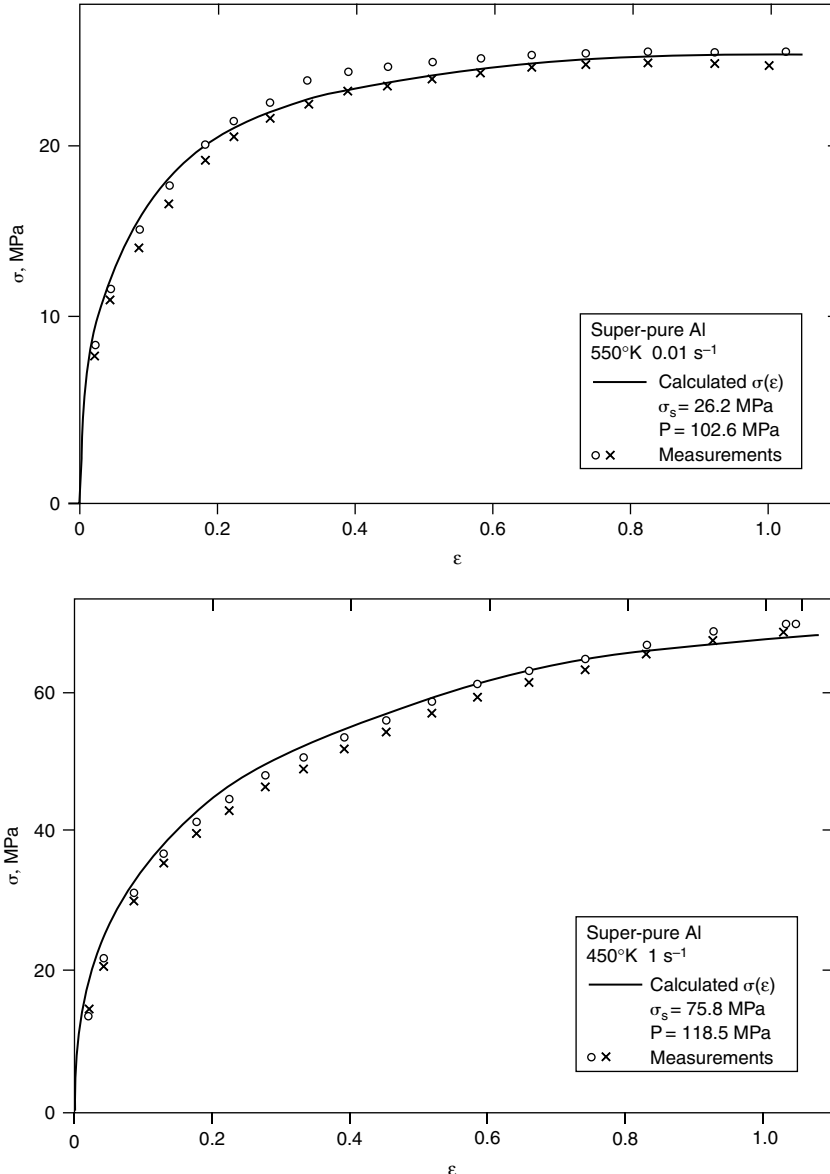

Fig. 19 Correspondence between  $\sigma(\epsilon)$  evaluated on the basis of Eq 55 and the measured curve

be used; as a first approximation,  $\sigma_0$  can be set equal to the yield stress under the conditions of interest.

## Diffusional Flow Mechanisms

### Creep (Ref 32)\*

**Nabarro-Herring Creep.** Dislocation glide creep involves no atomic diffusional flow. Nabarro-Herring creep is the opposite of dislocation glide creep in that Nabarro-Herring creep is accomplished solely by diffusional mass transport. Nabarro-Herring creep dominates creep processes at much lower stress levels and higher temperatures than those at which creep is controlled by dislocation glide. Because it does not devolve on dislocation glide, Nabarro-Herring creep is also observed in amorphous materials. However, discussion of Nabarro-Herring creep is facilitated by considering first how it is accomplished in a crystalline material subjected to the stress state shown in Fig. 21.

The grain illustrated in Fig. 21 may be considered either an isolated single crystal or an individual grain within a polycrystal. As indicated, the lateral sides of the crystal are assumed to be subjected to a compressive stress, and the horizontal sides to a tensile stress. The stresses alter the atomic volume in these regions; it is increased in regions experiencing a tensile stress and decreased in the volume under compression. As a result, the effective activation energy for vacancy formation is altered by  $\pm \sigma\Omega$ , where  $\Omega$  is the atomic volume, and the  $\pm$  signs refer to compressive and tension regions, respectively. Thus, the fractional vacancy concentration in the tensile and compressively stressed regions is given as:

$$N_v(\text{tension}) \cong \exp\left(-\frac{Q_f}{kT}\right) \exp\left(\frac{\sigma\Omega}{kT}\right) \quad (\text{Eq 61})$$

and

$$N_v(\text{compression}) \cong \exp\left(-\frac{Q_f}{kT}\right) \exp\left(-\frac{\sigma\Omega}{kT}\right) \quad (\text{Eq 62})$$

where  $Q_f$  is the vacancy-formation energy. Provided the grain boundary is an ideal source or sink for vacancies if the grain of Fig. 21 is a polycrystal or, if it is a single crystal, if the surface of it behaves likewise, the vacancy concentrations given by Eq 61 and 62 are maintained at the horizontal and lateral surfaces. The different concentrations at the surfaces drive a net flux of vacancies from the tensile to the compressively stressed regions, and this is equivalent

to a net mass flux in the opposite direction. As illustrated in Fig. 21(b), this produces a change in grain shape. The grain elongates in one direction and contracts in the other; that is, creep deformation occurs.

The creep rate resulting from this process is estimated as follows. The vacancy flux,  $J_v$ ,

through the crystal volume is given by:

$$J_v = -D_v \left( \frac{\delta N_v}{\delta x} \right) \quad (\text{Eq 63})$$

where  $D_v$  is the vacancy diffusivity [ $= D_{0v} \exp(-Q_m/kT)$ , where  $Q_m$  is the vacancy motion

Fig. 20  $\sigma(\epsilon)$  curves for a commercial ferritic stainless steel at various temperatures; experimental measurements compared with curves evaluated from Eq 55

Fig. 21 Nabarro-Herring creep results from a higher vacancy concentration in regions of a material experiencing a tensile stress vis-à-vis regions subject to a compressive stress. (a) This results in a vacancy flux from the former to the latter areas, and a mass flux in the opposite direction. (b) The resulting change in grain dimensions is equivalent to a creep strain.

energy] and  $\delta N_v/\delta x$  is the vacancy gradient. The term  $\delta x$  can be taken as a characteristic diffusion distance that is proportional to the grain size,  $d$  (compare with Fig. 21a), whereas  $\delta N_v$  is given as the difference of Eq 61 and 62. Multiplication of Eq 63 by the diffusion area (proportional to  $d^2$ ) gives the volumetric flow rate  $\delta V/\delta t$ ;  $\delta V/\delta t$  represents the volume transferred per unit time from the lateral to the horizontal sides of the crystal. According to this reasoning, it is given by:

$$\frac{\delta V}{\delta t} \cong -D_{0v}d \exp\left[-\frac{Q_f + Q_m}{kT}\right] \times \left[\exp\left(\frac{\sigma\Omega}{kT}\right) - \exp\left(-\frac{\sigma\Omega}{kT}\right)\right] \quad (\text{Eq 64})$$

The change in length ( $\delta d$ ) of the crystal along the tensile axis is related to  $\delta V$  by  $\delta V \cong d^2 \delta d$ . The corresponding Nabarro-Herring creep rate ( $\dot{\epsilon}_{\text{NH}}$ ) is expressed as  $1/d(\delta d/\delta t)$ ; thus:

$$\dot{\epsilon}_{\text{NH}} = \left(\frac{D_{0v}}{d^2}\right) \exp\left[-\frac{Q_f + Q_m}{kT}\right] \times \left[\exp\left(\frac{\sigma\Omega}{kT}\right) - \exp\left(-\frac{\sigma\Omega}{kT}\right)\right] \quad (\text{Eq 65})$$

The term  $D_{0v} \exp[-(Q_f + Q_m)/kT]$  of Eq 65 is identically equal to the lattice self-diffusion coefficient,  $D_L$ . Moreover, at the high temperatures and low stresses at which Nabarro-Herring creep is important,  $\sigma\Omega$  is much less than  $kT$ , so that  $\exp[\pm\sigma\Omega/kT] = 1 \pm \sigma\Omega/kT$ . Using these relations, and letting a constant  $A_{\text{NH}}$  represent geometrical factors that are only incompletely considered,  $\dot{\epsilon}_{\text{NH}}$  can be written as:

$$\dot{\epsilon}_{\text{NH}} = A_{\text{NH}} \left(\frac{D_L}{d^2}\right) \left(\frac{\sigma\Omega}{kT}\right) \quad (\text{Eq 66})$$

As mentioned, Nabarro-Herring creep is important at high temperatures and low stresses, that is, in the temperature-stress regime where dislocation glide is not important. It is more important in creep of ceramic materials than in metals. This is the case because glide mechanisms of creep can be considered competitive with Nabarro-Herring creep, and dislocation glide is generally more difficult to effect in ceramics than in metals.

**Coble creep** is closely related to Nabarro-Herring creep. Coble creep is driven by the same vacancy concentration gradient that causes Nabarro-Herring creep. However, in Coble creep, mass transport occurs by diffusion along grain boundaries in a polycrystal or along the surface of a single crystal. For polycrystals, the diffusion area is thus proportional to  $\delta'd$ , where  $\delta'$  is an appropriate grain-boundary thickness. Analysis similar to that employed previously yields an expression for Coble creep:

$$\dot{\epsilon}_C = A_C \exp\left(-\frac{Q_f}{kT}\right) D_{0\text{GB}} \left[\exp\left(-\frac{Q_m}{kT}\right)\right] \times \left(\frac{\delta'}{d^3}\right) \left(\frac{\sigma\Omega}{kT}\right) = A_C \left(\frac{D_{\text{GB}}\delta'}{d^3}\right) \left(\frac{\sigma\Omega}{kT}\right) \quad (\text{Eq 67})$$

In Eq 67,  $Q_f$  represents, as it did previously, the vacancy formation energy, but  $Q_m$  represents the energy of atomic motion along the boundary. Thus, the exponentials containing these terms have been incorporated into  $D_{\text{GB}}$ , which represents an effective grain-boundary diffusivity (or surface diffusivity if a single crystal is considered). As indicated by Eq 67, Coble creep is more sensitive to grain size than is Nabarro-Herring creep. Thus, even though both forms of creep are favored by high temperature and low stress, it is expected that Coble creep will dominate the creep rate in very fine-grained materials. In the general case, the creep rate due to diffusional flow should be considered a sum of  $\dot{\epsilon}_{\text{NH}}$  and  $\dot{\epsilon}_C$ , because the mechanisms operate in tandem; that is, they are parallel creep processes.

### Creep Mechanisms Involving Dislocation and Diffusional Flow (Ref 32)

The linear dependence of creep on stress predicted by the previously mentioned mechanisms is not observed for many materials under conditions of moderate applied stress and temperature. Instead, the value of the stress exponent  $m'$  is found to range from approximately 3 to 7 (with  $m' = 4.5$  being observed as often as not).

Under these conditions, creep involves dislocation-recovery processes. Numerous dislocation mechanisms for creep have been postulated, and although it has been difficult to experimentally verify their applicability in individual cases, several of the mechanisms discussed in this section are physically appealing, and they, or similar processes, undoubtedly occur during dislocation creep. The mechanisms described are useful, too, for illustrating the strong stress dependence of dislocation creep.

**Nabarro-Herring Creep of Subgrains.** If a subgrain structure is developed, as it often is, during creep, then Nabarro-Herring creep of subgrains can occur. Provided each dislocation in the subboundary is an ideal source and sink for vacancies, the subgrain size,  $d'$ , substitutes for the grain size in Eq 66 and 67. It has been observed experimentally that  $d'$  is inversely related to stress, that is,  $d' \cong K/\sigma$ , where  $K$  is a material constant. Thus, when mass transfer occurs by volume diffusion, the subgrain creep rate ( $\dot{\epsilon}_{\text{sg}}$ ) is given as:

$$\dot{\epsilon}_{\text{sg}} = A_{\text{sg}} D_L \left(\frac{\sigma^2}{K^2}\right) \left(\frac{\sigma\Omega}{kT}\right) \quad (\text{Eq 68})$$

and  $m'$  for this type of creep is 3.

**Dislocation Glide-Climb Mechanisms.** As mentioned, creep can conveniently be viewed as a manifestation of competitive work hardening and recovery. The work-hardening aspects of creep are related to factors involving dislocation glide. Recovery aspects are related to nonconservative dislocation motion, for exam-

ple, dislocation climb in which obstacles to dislocation motion are circumvented and/or by which dislocations are annihilated—that is, removed from the structure.

Because the processes are sequential, the creep rate in a coupled glide-climb process is determined by the lesser of the glide-climb rates. In some cases, glide controls creep rate. For example, dislocation glide creep is controlled solely by glide, because no atomic mass transport is involved in this type of creep. Even at higher temperatures, creep may be limited by glide. At certain stress-temperature combinations, for example, solute atoms are able to diffuse at velocities comparable to those of moving dislocations. In these circumstances, the solute concentration in the dislocation vicinity far exceeds the average concentration, and the resulting solute drag markedly increases lattice resistance to dislocation motion. As a consequence, the glide velocity is less than the climb velocity.

Most coupled creep mechanisms, however, are climb controlled; that is, the dislocation climb velocity is less than the glide velocity. One potential mechanism is illustrated in Fig. 22, where  $X$  dislocation sources per unit volume emit dislocations that glide a distance  $L$  in their slip plane. These interact with similar dislocations emitted from sources on parallel slip planes separated vertically by the distance  $h$ . Consistent with the constant dislocation structure associated with creep, each source is assumed to have a fixed number of loops around it. Thus, continued emission of dislocations from the sources (i.e., continued glide) is dependent on the annihilation rate of the outermost dislocations. Annihilation is effected by climb over the distance  $h$ . Dislocation pairs of the type  $\left[\begin{smallmatrix} + \\ - \end{smallmatrix}\right]$  climb and annihilate each other by addition of solute atoms (i.e., removal of vacancies) to the atomic planes separating them. Conversely, dislocation pairs of the type  $\left[\begin{smallmatrix} - \\ + \end{smallmatrix}\right]$  on the opposite side of the loop are removed by addition of vacancies (i.e., removal of solute atoms) between their respective planes. Thus, the climb process involves mass transfer from one side of the loop to the other.

The strain rate associated with this process can be written in the conventional form:

$$\dot{\epsilon} = \rho b v_g \quad (\text{Eq 69})$$

where  $\rho$  is the dislocation density, and  $v_g$  is the dislocation glide velocity, which is less than the climb velocity  $v_c$ . Climb and glide are coupled, and it can be shown that  $v_g$  and  $v_c$  are related through the geometrical ratio  $h/L$  as  $v_g = \frac{h}{L} v_c$ , where it is assumed that  $L > h$ . The dislocation density is obtained by multiplication of  $X$  by the average loop diameter ( $\cong L$ ) and the number of loops per source, which can be shown to be proportional to  $L/h$ ; thus:

$$\dot{\epsilon} \sim \frac{XL^3}{h^2} v_c \quad (\text{Eq 70})$$

where  $X$  is the number of dislocation sources per unit volume. Moreover,  $X$  multiplied by the

**Fig. 22** (a)  $X$  dislocation sources per unit volume emit dislocations over a radius  $L$ . Continued emission (and hence strain) requires that the outermost dislocations in each loop be annihilated by climb processes between nearby loops separated by the distance  $h$ . (b) A two-dimensional view of the loop array illustrating how the climb process results in dislocation annihilation. Adapted from Ref 33

volume per source ( $\cong \pi L^2 h$ ) is constant, or  $L \cong (Xh)^{-1/2}$ . Hence:

$$\dot{\epsilon} \sim \frac{v_c}{h^{3.5} X^{1/2}} \quad (\text{Eq 71})$$

Dislocation climb is driven by stress fields similar to those driving diffusional creep. Thus, if mass transfer occurs by volume diffusion,  $v_c$  is given by:

$$v_c \sim D_L \left[ \exp\left(\frac{\sigma\Omega}{kT}\right) - \exp\left(-\frac{\sigma\Omega}{kT}\right) \right] \cong 2D_L \frac{\sigma\Omega}{kT} \quad (\text{Eq 72})$$

and the glide-climb creep rate,  $\dot{\epsilon}_{GC}$ , can finally be written as:

$$\dot{\epsilon}_{GC} = \frac{A_{gc} D_L}{h^{3.5} X^{1/2}} \left( \frac{\sigma\Omega}{kT} \right) \quad (\text{Eq 73})$$

The distance  $h$  is thought to scale inversely with stress. Thus, if  $X$  is assumed independent of stress, the exponent  $m'$  for this type of dislocation creep is 4.5, and this is in accord with considerable experimental evidence.

### General Equation Form

In spite of the apparent diversity of the formulations for the several creep rates presented in this section, all of them can be expressed in a similar form, that is:

$$\dot{\epsilon}_i = A_i D_i \left( \frac{\sigma}{\mu} \right)^{m''} \left( \frac{\sigma\Omega}{kT} \right) \left( \frac{b}{d} \right)^{n'} \quad (\text{Eq 74})$$

**Table 2** Values of the parameters  $m''$  and  $n'$  and approximate values of the constant  $A_i$  in the expression for the steady-state creep rate  $A_i D_i (\sigma/\mu)^{m''} (\sigma\Omega/kT)(b/d)^{n'}$

Mechanism	Favored by	$A_i (m^{-2})$	$m''$	$n'$
Nabarro-Herring (NH) creep	High temperature, low stress, and large grain sizes	$7(\Omega)^{-2/3}$	0	2
Coble creep	Low stress, fine grain sizes, and temperatures less than those for which N-H creep dominates	$50(\Omega)^{-2/3}$	0	3
Nabarro-Herring creep of subgrains	High temperature and stresses such that the subgrain size is less than the grain size. (Subgrain size, $d'_s$ , scales with stress approximately as $d'_s = 20(\mu b/\sigma)$ )	$0.01(\Omega)^{-2/3}$	2	0
Generalized power-law creep	High stress, lower temperatures in comparison to Coble creep, and large grain sizes	(Several to several million) $\times (\Omega)^{-2/3(a)}$	2–6(a)	0

(a) The terms  $A_i$  and  $m''$  are strongly dependent on the mechanism controlling power-law creep at the substructural level. Adapted from Ref 34

In Eq 74, the last three parameters on the right-hand side are dimensionless. As mentioned, the ratio  $\sigma\Omega/kT$  is the ratio of a mechanical to a thermal energy. The parameter  $(b/d)^{n'}$ , where  $b$  is the Burgers vector, represents a grain-size dependence of creep; for example,  $n' = 2$  for Nabarro-Herring creep and  $n' = 0$  for dislocation climb-glide creep. The term  $\sigma/\mu$  is the ratio of the applied stress to the shear modulus; this ratio is important in determining the creep rate when dislocations are involved in creep (note that  $m'' = 0$  for diffusional creep).

The diffusion coefficient,  $D_i$  of Eq 74, is usually the volume diffusion coefficient (Coble creep is an exception), and  $A_i$  has dimensions of  $m^{-2}$ . Thus,  $A_i^{-1}$  can be considered a measure of the diffusion area. The coefficients  $m''$  ( $= m' - 1$ ),  $n'$ , and approximate values of  $A_i$  are

listed in Table 2 for the mechanisms described in this section. Comments in the table also indicate the approximate stress, temperature, and, if appropriate, grain-size regimes in which a particular mechanism may be expected to dominate the creep rate.

Although Table 2 is useful for clarifying to some extent the conditions under which a particular creep mechanism is most important, a graphical description is usually preferable, such as by representation in so-called deformation mechanism maps.

**Grain-boundary sliding accommodated by diffusional flow** is the superplastic analog of Nabarro-Herring and Coble creep. As proposed originally by Ashby and Verrall (Ref 35), grain shape is preserved during superplastic deformation by a grain-switching mechanism that also

**Fig. 23** The grain-switching mechanism of Ashby and Verrall. Relative grain-boundary sliding produces a strain (c) without a change in shape of the grains (compare a with c). However, the intermediate step (b) of the process is associated with an increased grain-boundary area. Source: Ref 35

provides for the resulting strain. The grain-switching mechanism is illustrated in Fig. 23, which shows a two-dimensional configuration of four grains before (Fig. 23a), after (Fig. 23c), and at an intermediate state (Fig. 23b) of the grain-switching process. For the geometry illustrated, a true tensile strain of 0.55 is effected by the grain-switching event. The intermediate stage of the process illustrates several significant microstructural features of the switching mechanism. First, there is an increase in grain-boundary area in the intermediate state as compared to the initial and final states. This results in a threshold stress below which grain switching cannot occur. In effect, the applied stress must perform a component of irreversible work associated with the formation of the increased grain-boundary area, and this stress must be exceeded in order for additional stress to drive diffusional flow.

Second, diffusional flow provides for the shape accommodation necessitated by the intermediate state (Fig. 24). In the Ashby-Verrall model, the flow can be either within grains (analogous to Nabarro-Herring creep) or along the grain boundaries (analogous to Coble creep). Provided the applied stress is considerably in excess of the threshold stress, the strain rate for the grain-switching mechanisms exceeds considerably that due to conventional creep mechanisms. This is related to several geometrical features of grain switching. First, the volume of material that must be transported to effect a given strain via grain switching is approximately  $1/7$  that required for diffusional creep. Additionally, the grain-switching diffusion distance is reduced by a factor of approximately 3 vis-à-vis the diffusional-creep distance, and there are six such paths for grain switching as opposed to four for diffusional creep.

Although these factors are mitigated to a degree by the fact that some of the grain

boundaries are at angles of neither 0 nor  $90^\circ$  to the tensile axis (thus reducing the effective driving stress for diffusional flow), the net result is that the strain rate for the grain-switching mechanism is approximately an order of magnitude higher than it is for diffusional creep. Ashby and Verrall, considering both volumetric and grain-boundary mass transport, developed the following constitutive equation to describe the grain-switching creep rate:

$$\dot{\epsilon}_{GS} \cong \frac{100\Omega}{kTd^2} \left( \sigma - \frac{0.72\gamma}{d} \right) D_L \times \left( 1 + \frac{3.3\delta'D_{GB}}{dD_L} \right) \quad (\text{Eq 75})$$

The term  $0.72\gamma/d$  represents the threshold stress for the grain-switching event. If only boundary transport is important (i.e., if  $3.3\delta'D_{GB} \gg dD_L$ ), Eq 75 reduces to:

$$\dot{\epsilon}_{GS} \cong \frac{330\Omega}{kT} \frac{\delta'D_{GB}}{d^3} \left( \sigma - \frac{0.72\gamma}{d} \right) \quad (\text{Eq 76})$$

and the grain-switching mechanism can be considered competitive with ordinary Coble creep. Grain switching dominates Coble creep at stresses large in comparison to  $0.72\gamma/d$  and vice versa.

Grain-switching creep, as described by Eq 76, is also competitive with ordinary dislocation creep, with the latter dominating at high stress levels. This leads to stress-strain-rate behavior very similar to that shown in Fig. 25. In region I, grain switching dominates, and  $\sigma \cong \sigma_0 + A\dot{\epsilon}$ . Likewise, dislocation creep dominates region III, and the transition region II is characterized by a rapid increase in stress with strain rate and associated superplastic behavior. The overall scheme as envisaged by Ashby and Verrall is summarized in Ref 35.

Grain-switching events have been observed in emulsions and in thin films of the superplastic zinc-aluminum metallic alloy. The mechanism is also conceptually appealing, because it predicts the generally observed stress-strain-rate relationship. Additionally, it does not, except as a transition event, invoke dislocation mechanisms, and, in view of the absence of observed concentrated dislocation activity in superplastic materials, this was for some time considered additional support for the grain-switching mechanism. It was also realized that dislocation and diffusional flow accommodation could occur concurrently. However, the grain-switching model is not without its shortcomings. For example, it generally does not predict accurately the stress level of region I. Nor, for that matter, does it consider in detail the previously mentioned dislocation accommodation, and recent studies have revealed dislocation activity, especially in the grain-boundary vicinity, in

**Fig. 24** During the intermediate stage of grain switching, grains 1 and 2 (compare with Fig. 23) change their shape from that indicated by the solid (initial state) lines to that of the dotted lines. The shape change is provided for by diffusional flow, which can take place by volumetric or boundary diffusion. Source: Ref 35

superplastically deformed materials. A qualitative description of accommodation provided by dislocation flow is therefore provided in the next section.

**Grain-Boundary Sliding Accommodated by Dislocation Flow.** Models of superplasticity that invoked accommodation by dislocation flow were developed even before microscopic observations confirmed dislocation activity in superplastic materials. This was a natural result of the realization that creep strains can also be accommodated by dislocation flow. The accommodation mechanisms advanced for superplasticity are similar in some respects to those expected in dislocation climb-glide creep processes. They must, however, provide for a means by which grain shape remains unaltered during straining. It is significant, too, that in contrast to dislocation creep mechanisms, grain size is explicitly recognized as important in relating strain rate to stress. This arises because, at the low stress levels associated with superplastic deformation, the grain size of a superplastic material is expected to be less than the cell or subgrain size.

The absence of a grain substructure does not, per se, eliminate dislocation activity during superplastic deformation. It only means that the characteristic diffusion distance of dislocation accommodation is that of the grain dimension.

As a consequence, several of the dislocation models for superplasticity arrive at a constitutive equation of the form:

$$\dot{\epsilon}_{DS} = C_1 D \frac{\sigma \Omega}{kT} \frac{\sigma}{\mu} \left( \frac{b}{\bar{d}} \right)^2 \quad (\text{Eq 77})$$

where the constant  $C_1$  depends on the details of the model, and the diffusivity  $D$  is usually a grain-boundary diffusion coefficient. Such descriptions are reasonable with respect to the magnitude of the stress required to produce a given strain rate, the  $m$  value of 0.5, and the grain-size dependence of strain rate. In common with the Ashby and Verrall model, dislocation models for superplasticity consider region III to be controlled by conventional dislocation creep. In contrast to the grain-switching model, however, region II is viewed as controlled by an independent mechanism and is not considered a transition stage from region I to region III.

According to the dislocation models of superplasticity, the transition from region II to region III happens when the subgrain size becomes less than the grain size. For several materials, the inverse relationship between subgrain size,  $d'$ , and stress is approximated by:

$$\frac{d'}{b} = 10 \frac{\mu}{\tau} \quad (\text{Eq 78})$$

and Eq 78 therefore defines the stress for the transition from superplasticity to dislocation creep. That this reasonably describes observed transitions is confirmed by Fig. 26(a) and (b) (Ref 36), which are deformation mechanism maps (in terms of  $d/b$  versus  $\tau/\mu$  for the superplastic aluminum-zinc and lead-tin alloys. The dotted lines in these diagrams represent the transition predicted by Eq 78, and it is seen that it describes well the experimental results. Figures 26(a) and (b) also show that superplastic flow is competitive with diffusional creep and dominates it at higher stress levels. Although region I is shown as separate areas in these figures, there is disagreement among the dislocation advocates of superplasticity as to whether it represents a separate flow mechanism or is merely an obscure manifestation of Coble creep.

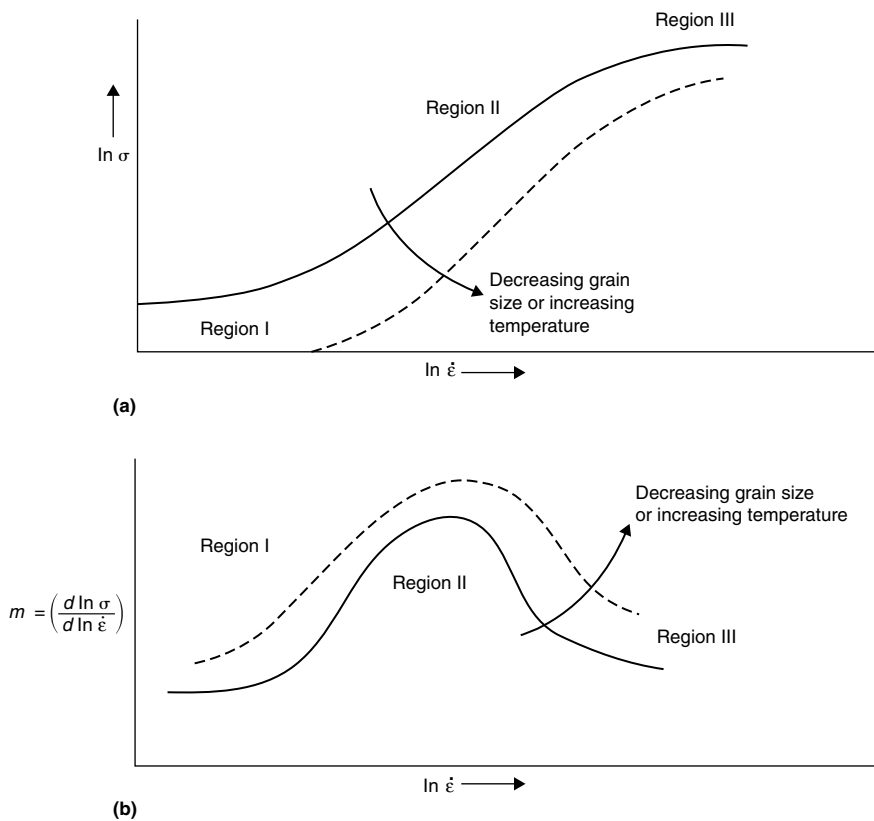

Although no model of superplasticity is able to describe accurately the phenomenon in all of its quantitative and qualitative aspects, the models discussed are nonetheless useful from a technological viewpoint. In effect, they can predict approximately the grain size, temperature, and strain-rate regimes where superplasticity is likely to be observed, and this has proven useful in engineering applications. Indeed, superplastic forming of commercial aluminum-, titanium-, and nickel-base high-temperature alloys is done routinely, and this process could not be considered without appropriate constitutive equations. One drawback of superplastic forming, though, is the (frequently) low strain rates used in the process. These result in low production rates and correspondingly higher costs.

### Grain Growth Effects (Ref 37)

As shown by Eq 77, grain growth during superplastic flow can have a significant effect on the strain rate developed under a given imposed stress. A detailed investigation of such an effect was conducted by Ghosh and Hamilton (Ref 37) for Ti-6Al-4V. Hot tension tests were conducted on material with three different starting alpha-grain (particle) sizes. The grain growth during deformation at constant strain rate was determined by quantitative metallography. To obtain a unified view of grain-growth behavior, the results for each initial grain size (Fig. 27) were translated along the time abscissa such that the initial grain size on these plots came to rest on the corresponding plots in Fig. 28 (i.e., for the same strain rate in each case). The resulting log (grain size) versus log (time) plots are shown in Fig. 29. The approximation to linear behavior in these plots is reasonable, thus suggesting the relationship:

$$d = d_0 (t/10)^n \quad (\text{Eq 79})$$

where  $d$  is the current grain size,  $d_0$  is the initial grain size, both in micrometers,  $t$  is time in minutes, and  $n$  is a parameter that increases with increasing strain rate. An approximate value for

**Fig. 25** (a) The low stress-strain-rate behavior of a material manifesting superplasticity. In regions I and III, the strain-rate sensitivity (b) is fairly small, whereas it is high in region II where superplasticity is observed. As indicated in (a), increases in temperature or decreases in grain size shift the  $\sigma$ - $\dot{\epsilon}$  curve downward and to the right. The same changes produce a somewhat higher value of  $m$ , as shown in (b).

this parameter for Ti-6Al-4V at 927 °C (1700 °F) is found to be:

$$n = 1.8 (\dot{\epsilon}_t + 0.00005)^{0.237} \quad (\text{Eq 80})$$

where  $\dot{\epsilon}_t$  has the dimension of  $\text{s}^{-1}$ . Equations 79 and 80 are used subsequently in developing a constitutive equation for superplastic flow in this material.

With evidences of hardening as well as grain growth during deformation available, an attempt is now made to relate the two in Fig. 30. This was done by cross plotting flow stress from Fig. 31 against grain size during deformation, obtainable from the grain growth kinetics plots of Fig. 27 and 28 (for each applied strain rate). The solid curves in Fig. 32 are thus grain-growth hardening curves for initial grain sizes of 6.4, 9, and 11.5  $\mu\text{m}$  for the various applied strain

rates. The flow stress corresponding to each initial grain size is indicated by a data point taken from the “knee” between the elastic and grossly plastic parts of the load-extension plots and represents as much as 3% total strain. While there is some subjectivity in determining these points, the errors are no more than  $\pm 1$  MPa (0.15 ksi).

### Physical Model for Superplastic Flow (Ref 38)\*

Research on the mechanism of superplastic flow in fine-grain metals has encompassed many ideas, such as diffusional creep (Ref 39–41), dislocation creep (Ref 42, 43) with diffusional accommodation at grain boundaries (Ref 35),

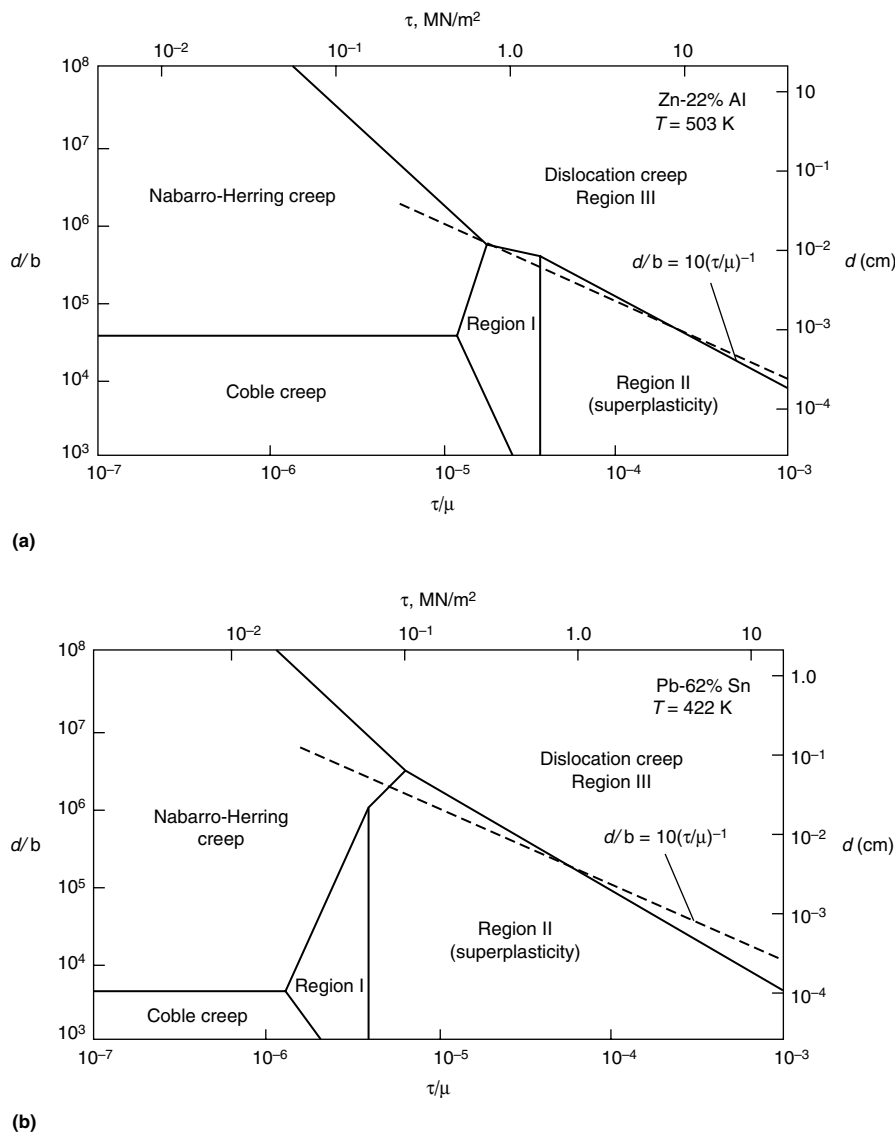

concepts of grain-mantle deformation (Ref 44, 45), and so on. While these have broadened the view of the underlying physics of micrograin superplasticity, controversy still exists on the details of the microscopic process of deformation. A few known facts are:

- Sliding of grains along grain boundaries is observed (Ref 46)
- Both grain stretching and dynamic grain growth accompany superplastic deformation (Ref 37, 47)

With respect to the mechanical response under optimal superplastic conditions, the peak value of  $m$  ( $d \log \sigma / \log \dot{\epsilon}$ ) can be 0.7 to 0.8 for fully recrystallized single-phase alloys (typical grain size  $\sim 6$  to 15  $\mu\text{m}$ ), and can be as low as 0.4 to 0.6 for very fine-grain (and subgrain-containing) alloys with a large amount of dispersoid particles (grain size  $\sim 0.5$  to 4  $\mu\text{m}$ ), with a bell-shaped distribution of  $m$  as a function of strain rate (Ref 48, 49). The existing superplastic deformation models are unsatisfactory in terms of explaining values of  $m > 0.5$ . These steady-state models ignore microstructural evolution, which is integral to the deformation process. Furthermore, for most alloys, the  $m$  value is usually high, over several decades in strain rate, which does not agree with predominantly diffusion-based models, for example, the Ashby-Verrall model (suitable for  $m > 0.5$ ).

While grain-boundary shear and sliding are important to the superplastic deformation process, the grain neighbor-exchange process (Ref 43, 46) is regarded primarily as a surface phenomenon due to lower constraints at the free surface. Any interior neighbor-exchange effect is small and results from a combined effect of concurrent grain growth and grain-boundary sliding, which causes smaller grains to shrink and move out of the path of larger growing grains. Fine-grain alloys whose grain boundaries are typically pinned by dispersoid particles often show grain-boundary migration during superplastic deformation, resulting in unpinning of boundaries from the particles. The mechanical effects and the microstructural evolution processes mentioned here are intrinsic to the superplastic deformation process and must be incorporated into a general theory of deformation of polycrystalline metals.

A new model to address this from the viewpoint of dislocation micromechanics is described here based on the following. At elevated temperature, the grain-boundary bonds are weakened, and yet shear and normal stresses must be transferred across them. Thus, inelastic displacement in grain-boundary regions must be larger than those within the grain interior, which may even remain elastic. This view is essentially the same as the grain mantle versus core deformation model proposed by Gifkins (Ref 44).

**Fig. 26** Deformation mechanism maps for (a) zinc-aluminum and (b) lead-tin in terms of grain size versus stress. According to the dislocation mechanisms of superplasticity, a transition from superplasticity to dislocation creep should occur when  $d/b \cong 10 \mu/\tau$ . This is approximately observed for these materials. Source: Ref 36

\*Adapted with permission from: A.K. Ghosh, A New Physical Model for Superplastic Flow, *Materials Science Forum*, 1994, p 39–46

While diffusion of atoms is critical to the deformation process, it is not believed that large-scale atom transport (Ref 35, 39, 41) occurs to any appreciable extent in metallic alloys. Figures 33(a) and (b) schematically show this new concept of mantle and core regions. Due to the higher defect density and weakened bonds, the diffusivity in the mantle region can be very high (close to grain-boundary diffusivity). Arrows within the mantle region in Fig. 33(a) indicate the direction of the tensile component parallel to the boundary. Local inelastic shear within the mantle, and atom transport, are also in the direction of these arrows, and marker line

offsets are created (from  $ab$  to  $d'b'$ ) during superplastic deformation. The details of the atom transport, however, involve both glide and climb, as explained subsequently.

Figure 33(b) shows how grain-boundary sliding may be resisted at grain-boundary steps, ledges, and particles (not shown). Stress concentration leads to initiation of glide along slip planes in the favored orientations. Thus, discontinuities such as ledges, nondeformable particles, and dispersoids on the grain boundaries act as dislocation sources. At low stresses, glide velocities of the dislocations are low, and therefore, these dislocations can climb out

of their planes toward the grain boundaries (lower chemical potential) before they have a chance to glide into the grain core. The rows of atoms, as they arrive at the grain boundary, can plate on the boundary as well as travel along the boundary away from the ledge that produced them. The rise of the subsurface atoms to the grain-boundary surface helps them attach preferentially to the grain steps and ledges existing on a concave inward boundary, thus leading to boundary migration and enhanced concurrent grain growth. Grain-boundary sliding and grain growth are thus tied to the same mantle deformation process. The sliding strain is directly tied to extension of the grains due to atom flow, not additive to it. When applied stresses are high, some dislocations can still climb to the nearest grain boundaries, but many more travel across the grain to cause grain core deformation via conventional climb-guide creep. Kinetics of these processes are given as follows.

**Low-Stress Behavior.** Stress concentration at grain-boundary discontinuities is a function of their size and spacing. The largest discontinuities initiate slip first at the lowest stresses. A popular view of source activation is by bowing of grain-boundary dislocation segments between their pinning points (particles, jogs, etc.) A source is activated when the local stress,  $\tau$ , exceeds  $\mu b/\lambda$ , where  $\mu$  is shear modulus,  $b$  is Burgers vector, and  $\lambda$  is spacing between pinning points. For a distribution in the value of  $\lambda$ ,  $\tau$  for source initiation ranges from a minimum value of  $\tau_0$  (for the largest  $\lambda$ ) to the largest value corresponding to the smallest  $\lambda$ . The number of activated sources,  $N$ , per grain boundary as a function of  $(\tau - \tau_0)$  will have a decaying slope approximated by a parabolic function:

$$N \propto (\tau - \tau_0)^q \quad (\text{Eq 81})$$

where  $q$  is the source activation exponent (0.1 to 1 depending on the alloy).

Fig. 27 Grain-growth kinetics at two different tensile strain rates compared with static kinetics for initial grain sizes 9.0 and 11.5  $\mu\text{m}$ , respectively

Fig. 28 Grain-growth kinetics at four different tensile strain rates compared with static kinetics for an initial grain size of 6.4  $\mu\text{m}$

Fig. 29 Grain-growth kinetics data from Fig. 27 and 28 have been reassembled in a log-log plot.

**Fig. 30** The change in flow stress as a function of grain size (changing during tensile test), indicated by solid curves. The data points indicate the three initial grain sizes from which tests were started. The appropriate strain rates are shown on the plot.

**Fig. 31** True stress-strain curves for three initial grain sizes of 6.4, 9, and 11.5  $\mu\text{m}$ , respectively. The bottommost curve shown is for a strain rate of  $5 \times 10^{-5}/\text{s}$ , and the topmost one for  $5 \times 10^{-3}/\text{s}$ , both for the 6.4  $\mu\text{m}$  grain size material. The dotted part indicates a significant strain gradient developing in the specimen.

The shear displacement rate,  $\dot{\gamma}_m$ , in the mantle may be expressed as:

$$\dot{\gamma}_m = b \cdot N \cdot v \quad (\text{Eq 82})$$

where  $b$  is the Burgers vector, and  $v$  is the glide velocity. As commonly assumed,  $v$  is proportional to climb velocity, which in turn is related to the volume transport rate of atoms per unit area of the grain boundary driven by the effective stress. It can be shown then that:

$$v \propto \frac{1}{d^2} \left[ \frac{D_m(\tau - \tau_0)\Omega}{kT} \right] \cdot \delta d \quad (\text{Eq 83})$$

where  $D_m$  is the effective diffusivity in the mantle region (similar to grain-boundary diffusivity),  $d$  is grain size,  $\delta$  is mantle width,  $\Omega$  is atomic volume,  $k$  is Boltzmann's constant,  $T$  is absolute temperature, and  $(\tau - \tau_0)\Omega$  represents chemical potential driving diffusional climb. Using Eq 81 to 83, the mantle shear strain rate,  $\dot{\gamma}_m$ , can be expressed as:

$$\dot{\gamma}_m \propto \frac{\dot{\gamma}_m}{d} \propto \frac{b}{d^2} \cdot (\tau - \tau_0)^q \left( \frac{\delta D_m \Omega}{kT} \right) (\tau - \tau_0) \quad (\text{Eq 84})$$

Because this strain rate directly leads to tensile strain rate, the mantle contribution to the tensile strain rate can be written as:

$$\dot{\epsilon}_m = (A/d^2)(\sigma - \sigma_0)^{1+q} \quad (\text{Eq 85})$$

**Fig. 32** A schematic representation showing how instantaneous measurements of  $m$  were made at periodic intervals during the tensile test, by strain-rate increments of 25%

where  $A \propto (b\delta\Omega D_m/kT)$  is constant for a fixed temperature,  $\sigma$  is tensile stress, and  $\sigma_0$  is the tensile equivalent of  $\tau_0$ . The value of  $q$  may vary between 0.1 and 0.4 for a well-recrystallized grain structure containing a small volume fraction of dispersoids, but for a recovered subgrain containing material with a high volume of fine dispersoids, the stress dependence of source activation can be greater ( $0.3 \leq q \leq 1$ ).

**Concurrent Grain Growth.** Dynamic grain growth in this model is directly related to the transport occurring from strain contribution due to the mantle region. This occurs in addition to the surface-energy-driven static grain growth. Thus, instantaneous grain size,  $d$ , may be given by:

$$d = d_0 + a\tau^p + \beta\epsilon_m \quad (\text{Eq 86})$$

Fig. 33 Schematic illustrations of mantle-core deformation model. (a) Atom transport along the direction of arrow leads to offsets in the marker line  $ab$ . New position of marker  $a'b'$  lies on deformed grains (not shown). (b) A portion of the mantle magnified to show local glide-and-climb effect initiated from grain-boundary steps A and B

where  $d_0$  is the initial grain size,  $t$  is time,  $a$  is a constant for static grain growth,  $p$  is a static grain growth exponent (typically 0.5),  $\epsilon_m$  is the strain contributed from mantle deformation, and  $\beta$  is a proportionality constant dependent on temperature, alloy chemistry, and dispersoid volume fraction.

**High-Stress Behavior.** At high stresses, climb transport is too slow to fully relieve stress concentration at grain boundaries. Dislocations, injected through the grain core, participate in the normal glide-climb creep process with a creep law similar to:

$$\dot{\epsilon} = K_1 \sigma^n e^{-Q/kT} \quad (\text{Eq 87})$$

where  $K_1$  is the standard constant for dislocation creep, and  $Q$  is the activation energy for dislocation creep. Stress concentration at grain corners cannot, however, be relieved by the general dislocation creep alone, and additional local deformation must occur at all grain corners where slip incompatibility develops. An estimate of this effect has been made in a previous paper (Ref 50), which suggests:

$$\dot{\epsilon}_c = (K + A_1/d^3) \sigma^n \quad (\text{Eq 88})$$

where  $\dot{\epsilon}_c$  is creep rate contributed by grain core, including accelerated deformation at grain corners,  $K$  is  $K_1 e^{-Q/kT}$ , and  $A_1$  is a constant relating to stress concentration and enhanced dislocation creep at grain corners. The term  $d^3$  arises due to the number of grain corners present per unit volume. The overall superplastic creep rate is then obtained by assuming that both mantle and

core deformation contribute to the overall deformation; that is:

$$\dot{\epsilon} = \dot{\epsilon}_m + \dot{\epsilon}_c \quad (\text{Eq 89})$$

If all relevant constants are known, Eq 85 and 88 can be combined with Eq 86 to obtain instantaneous stress-strain response as a function of applied strain rate. A simple computer program was developed to calculate stress, strain, and grain size incrementally in time for a given strain-rate history and material property parameters.

**Results of Simulation Experiments.** The model presented previously is used to stimulate mechanical and microstructural response of two aluminum-base alloys, similar to 7475 Al and a 7000-series alloy containing a large volume of chromium and zirconium intermetallic dispersoids (e.g.,  $\text{Al}_3\text{Zr}$ ,  $\text{Cr}_2\text{Al}_9$ ) (Ref 48, 51). Their compositions are given in Table 3.

The addition of a large volume of dispersoids suppresses nucleation of recrystallized grains in alloy 2, and a particle pinned subgrain structure forms. Thus, finer structures are typically associated with higher dispersoid volume, and the simulation is carried out with this realistic feature in mind. The experimental stress versus strain-rate data of these two materials in uniaxial tension are shown in Fig. 34. Alloy 2 has lower flow stresses than alloy 1, and the strain rate for its peak  $m$  ( $\sim 0.5$ ) is almost 2 orders of magnitude higher than that of alloy 1 (peak  $m \sim 0.8$ ). Note that alloy 3 in Fig. 34 is for a similar alloy containing only 0.2% Zr and no chromium. It has a

grain size of 6  $\mu\text{m}$  and appears to be more fully recrystallized than alloy 2.

Predictions of the Ashby-Verrall model for similar grain sizes (shown for comparison) do not provide an adequate match in slope with these. Their microstructure, stress-strain-rate data, and dynamic grain growth results were examined in detail to determine relevant parameters to be used to stimulate their behavior. Table 4 lists parameters representative of this general class of alloys without any attempt to exactly duplicate them for a specific alloy. The source activation exponent  $q$  is expected to increase with increased dispersoid content. While not directly measurable, its value for the two alloys is assumed to be 0.25 and 0.65, respectively. Also assumed is the value of  $A$ , which is maintained constant for the same type of alloy. All other parameters can be assessed from experimental data on these materials. Both static and dynamic grain growth for finer-grain alloy 2 are lower.

Figure 35 shows calculated stress-strain curves for alloy 1 for a variety of strain rates. Considerable strain hardening is observed at lower strain rates and very little hardening at the higher strain rates. It has been recognized recently that experimental strain measurements based on crosshead displacement are incorrect because of considerable stretching of material in the grip and specimen shoulder. Many existing data in the literature suffer from this problem. The reported strain-hardening rates are considerably higher than true hardening rates. This general behavior is in good agreement with results on superplastic materials (Ref 37, 48).

**Table 3** Chemical compositions of alloys for study

Material	Composition, wt%					Condition
	Zn	Mg	Cu	Zr	Cr	
Alloy 1 (7475 Al)	5.7	2.3	1.5	...	0.14	Fully recrystallized microstructure ( $d_0 = 12 \mu\text{m}$ )
Alloy 2 (7000+dispersoids)	7.2	2.5	2.0	0.3	0.3	Recovered subgrain structure ( $d_0 = 1.5 \mu\text{m}$ )

**Fig. 34** Experimental stress-strain-rate plots for two aluminum alloys (Table 3) having similar matrix chemistry. Calculated results for similar grain sizes are shown for comparison. The top solid line represents dislocation creep.**Table 4** Parameters for core-mantle model used in simulating behavior of two 7000-series aluminum alloys

Material parameters	Alloy 1	Alloy 2
	Low density of dispersoid particles; fully recrystallized grain structure	High density of dispersoid particles; recovered subgrain structure
Tensile threshold glide resistance, $\sigma_0$ (MPa)	0.08	0.12
Source activation exponent, $q$	0.25	0.65
Pre-exponential constant for mantle strain rate, $A$ ( $m^{-12} \text{MPa}^{-(1+q)} \text{s}^{-1}$ )	0.0075	0.0075
Constant for dislocation creep, $K$ ( $\text{MPa}^{-4} \text{s}^{-1}$ )	$1.18 \times 10^{-7}$	$1.18 \times 10^{-7}$
Stress exponent for dislocation creep, $n$	4	4
Constant for grain corner creep, $A_1$ ( $m^{-18} \text{MPa}^{-4} \text{s}^{-1}$ )	$0.5 \times 10^{-4}$	$0.5 \times 10^{-4}$
Initial grain size, $d_0$ ( $\mu\text{m}$ )	10	3
Static grain growth, $\alpha(p)$ , $\alpha(\mu\text{m}/\text{s})$	0.025 (0.5)	0.015 (0.5)
Dynamic grain growth, $\beta(\mu\text{m})$	5	3
Possible examples within the alloy category	7475 Al (Al-Zn-Mg-Cu) 5083 Al (Al-Mg-Mn) Al-33%Cu Zn-22%Al Ti-6Al-4V	7000 Al (Al-Zn-Mg-Cu)+dispersoids Al-Li-Zr alloys 2000 Al (Al-Cu)+dispersoids 5000 Al (Al-Mg)+dispersoids

The stress values from the early part of the stress-strain curves are plotted in Fig. 36(b) as a function of strain rate for both alloys 1 and 2. Note that the curve for alloy 2 is less steep. It also shows a peak  $m$  of  $\sim 0.6$  (Fig. 36a) at a strain rate of  $2 \times 10^{-3} \text{s}^{-1}$ , which is approximately 20 times faster than that for alloy 1. The calculated peak  $m$  for alloy 1 is approximately 0.8. These values as well as the general trend of data are in excellent

agreement with experimental observations. The wide range of strain rates over which alloy 2 shows a high  $m$  agree well with many results on superplastic alloys. Figure 37 shows the mantle strain rate ( $\dot{\epsilon}_m$ ) as a function of total applied strain rate for alloys 1 and 2. Below  $10^{-4} \text{s}^{-1}$ , deformation is entirely via mantle deformation. Above this rate, core deformation begins, more quickly for alloy 1 with gradual

exhausted source activation capability. The finer-subgrain-containing alloy does exhibit mantle deformation continuing to significantly higher strain rates.

The concurrent grain-growth behavior has been studied as a function of imposed strain rate and plotted in Fig. 38 and 39. As experimentally observed, the growth kinetics are accelerated by strain rate (Fig. 38a) and show the correct functional dependence. When plotted as a function of strain, the slower strain rates show larger grain size (Fig. 38b). Grain-growth kinetics normalized with respect to the initial grain size,  $d_0$ ,  $(\Delta d/\Delta t)d_0$ , are shown in Fig. 39 as a function of applied strain rate. The simulated results match data from several investigators well (Ref 37, 47, 52), showing that normalized grain-growth rate rises sharply at intermediate strain rates ( $10^{-4}$  to  $10^{-3} \text{s}^{-1}$ ). Comparing with Fig. 36, in this region of strain rates,  $m$  value begins to drop off rapidly.

Examination of flow stability was conducted by determining periodic  $m$  values from small step strain-rate (30% change) tests conducted during simulations from constant strain-rate tensile tests, and also by determining normalized slopes,  $(1/\sigma)(d\sigma/d\epsilon)$ , of stress-strain curves. These results are shown in Fig. 40. Figure 40(a) shows that  $m$  drops only slightly with increasing superplastic strain when  $m$  is high ( $\sim 0.7$ ). At higher strain rates, when  $m$  is lower (0.3 to 0.4) and mantle strain is smaller, the change in  $m$  is negligible. Figure 40(b) shows that  $(1/\sigma)(d\sigma/d\epsilon)$  at a strain rate of  $10^{-3} \text{s}^{-1}$  drops sharply as a function of strain and falls below 1 (maximum load point) at low strain; however, at a strain rate of  $10^{-6} \text{s}^{-1}$ , it decreases slowly, and maximum load is not reached before a strain of 0.4. Thus, flow stability is a result of concurrent grain growth and contributes to higher tensile elongation.

**Summary of Mantle-Core Model.** The new concept in the aforementioned mantle-core model of superplasticity is that dislocation sources are activated at the grain boundaries, and glide and climb in the grain-mantle region at low stresses control both grain-boundary sliding and concurrent grain growth. The model accurately predicts stress-strain-rate characteristics of metals with fully and partially recrystallized microstructures and strain-hardening characteristics. The details of grain-growth kinetics and flow stability are also simulated. This suggests that microstructural evolution is integrally connected with the superplastic deformation process.

# Springback

R.H. Wagoner, J.F. Wang, and M. Li, The Ohio State University

This article is intended as an introduction to the concepts of springback simulation as well as recommendations for its practice in a metal forming setting. Most of the developments focus on thin beams or sheets, where springback is most pronounced. The underlying mechanics of large-strain, elastic-plastic deformation are treated in a simplified, intuitive way, with numerous references provided for those wishing to delve into the theoretical underpinnings in more detail. Simple bending is first considered, along with a discussion of approximations, then bending with tension and finally, more complex numerical treatments. Compensation of die design to account for springback is also presented briefly.

This treatment is intended for practitioners with widely differing backgrounds and needs. The early treatments are suited to a limited class of problems but are best suited for understanding the direction of the effects of various material properties and process parameters. The roles and effects of various simplifying assumptions are also treated naturally with these closed-form solutions. The later treatments are intended to augment the practice of applied sheet forming

analysis (almost always finite element based) to include postforming springback analysis. As is shown, the choices of numerical parameters can be quite different for springback, so these aspects are emphasized.

As used throughout this article, *springback* refers to the elastically driven change of shape that occurs after deforming a body and then releasing it. The concept is understood by anyone who has manually bent a metal wire or strip. For a sufficiently small bend radius, some part of the bending remains after unloading and some part is recovered during unloading (or has sprung back). For bend radii larger than some critical value, the initial shape of the body is recovered. The recovered portion of the deformation is referred to as springback. As such, the definition inherently refers to a difference in geometry between the loaded state and the unloaded state.

The word *springback* as a single, unhyphenated word appears in virtually no standard dictionaries but has been in technical use since at least the early 1940s. A search of the internet in April 2005 found more than 26,800 occurrences of the word, and a contemporaneous search of the ISI Web of Science (Thomson

Scientific) of published technical papers located 334 such references appearing since 1980. These numbers represent increases of 460 and 27%, respectively, over similar searches performed 20 months earlier, in April 2003. Two inferences may be drawn: the technical meaning of springback is well established, although formal definitions appearing in dictionaries lag, and interest in springback is growing rapidly.

The definition of springback can be broad, applying to the action of springs, for example, but the principal technical intent of the word and interest in the phenomenon refers to the undesirable shape change that occurs after forming a part. The change is undesirable because it creates a difference of part shape from the tool shapes that were used to carry out the forming operation. If this difference is not predicted accurately and compensated for in the design of the tools, the part may not meet specifications.

Consideration of springback is of prime interest for bodies that have high aspect ratios; that is, at least one dimension is much larger than, or smaller than, the other dimensions. Examples include slender beams and thin sheets (Fig. 1, 2). For these cases, the overall geometric

**Fig. 1** Typical automotive sheet-formed part, the S-rail. (a) Formed part. (b) Finite element representation, as formed. (c) Cross-sectional schematics at three forming stages. Source: Ref 1

changes caused by springback can be very significant even though the elastic strains driving the springback can be tiny.

To introduce an applied example, Fig. 1(a) shows a representative automotive formed part referred to as the S-rail (Ref 1). Figure 1(b) depicts a corresponding finite element mesh, and Fig. 1(c) focuses on a schematic cross section of this part at three stages: initial (flat), as-formed (with tools in place), and unloaded (after springback). Inspection of the operation (and ignoring slight stretching at the top web of the part) reveals that the upper corners of the cross section are essentially bent to conform to the punch radius (the punch in this orientation lies below the sheet). When the tooling is removed, these radii open up to larger radii. This is typical of an idealized bending-with-tension operation. The sidewall regions of the formed rail or channel are drawn over the die radii (the die lies above the sheet in this orientation) over large distances, such that each element undergoes bending and unbending sequentially, also under the action of tension. When loaded, the sidewalls are flat. The final shape of the sidewalls incorporates what is known as sidewall curl. The level of tension for each location is related to the binder force, the friction with the tooling, and the work required to bend, unbend, and draw. If a draw bead were involved, this would add yet another element to the sheet tension determination.

The primary focus in this article is on sheet metal forming operations, such as the one shown in Fig. 1. This focus allows conclusions to be drawn with reference to a relatively narrow range of thicknesses and bend radii, both of which are small relative to the width of the body. The equations and results are nonetheless applicable to other geometries, with restrictions specified as necessary.

This article is organized in sections. The subject of springback is first addressed for the simplest, most easily understood cases, that is, pure bending of slender beams or sheets. While such treatments are applicable to few problems of applied interest, their study reveals the principles governing the problem and addresses the limitations of the various assumptions. To these treatments is then added the effect of superimposed tension, which is shown to be a critical variable for accurate prediction of springback. From these generally closed-form treatments, a leap is made to the much more general and practical prediction of springback for real forming operations, using either experience or finite element modeling. Finally, the design of dies and tooling using an assumed springback prediction capability is addressed.

## Pure Bending—Classical Results

In order to understand the phenomenon of springback, it is instructive to begin with the simplest case and the most restrictive assumptions. In this section, the case of pure, or simple, bending is considered, that is, bending under

the action of an applied moment without applied sheet tension. The springback consists of assumed elastic unbending on removal of the applied moment.

**Assumptions.** The assumptions that apply to this case in the simplest treatment may be listed as:

1. Plane sections remain planar.
2. No change in sheet thickness
3. Two-dimensional geometry, either plane strain or plane stress in width direction
4. Constant curvature (i.e., no instability of shape)
5. No stress in the radial, or through-thickness, direction
6. The neutral (stress-free) axis is the center fiber and is the zero-extension fiber.
7. No distinction between engineering and true strain
8. Isotropic, homogeneous material behavior
9. Elastic straining only during springback

The validity of these assumptions is discussed in the next section, but the simple results for springback under these conditions are first presented here.

Within these assumptions, the primary differences among treatments appearing in the literature relate to the assumed material constitutive behavior. There are two basic choices to be made: whether to treat the problem as purely plastic or elastic-plastic, and what form of stress-strain law to adopt in the plastic range. Results have been presented for nearly all choices: perfectly plastic (no hardening), linear hardening (Ref 2), power-law hardening (Ref 3–7), or a general approach (requiring graphical or other numerical integration) (Ref 8, 9).

**Basic Equations and Approach.** The approach is illustrated in Fig. 2. An initially flat sheet or beam is envisioned. For these purposes, a sheet denotes a part that is very wide relative to its thickness and bend radius and implies that the deformation is nearly plane strain; that is, the strain in width direction is zero. A beam denotes a part that is very narrow relative to thickness and bend radius and implies that the deformation is nearly plane stress; that is, the stress in the width direction is zero. The part is bent to a starting radius ( $R$ ) under the action of a moment ( $M$ ). The value of  $M$  acting on the sheet or beam is obtained by integrating the stress distribution as:

$$M = \int_{-t/2}^{t/2} \sigma_x(\epsilon_x) z w(z) dz \quad (\text{Eq 1})$$

where  $\epsilon_x$  is the circumferential strain,  $\sigma_x$  the circumferential stress (Fig. 2b),  $t$  is the sheet thickness, and  $w(z)$  is the width of the sheet, which in general may vary with the  $z$ -coordinate (that is, the cross section need not be rectangular). Assuming a rectangular cross section, taking advantage of the symmetry of the problem (assumptions 6 and 8 in the section “Approximations in Classical Bending Theory” in this article), and substituting into Eq 1 obtains the moment per unit width ( $M/w$ ), which may be expressed more simply:

$$\frac{M}{w} = \int_{-t/2}^{t/2} \sigma_x(\epsilon_x) z dz = 2 \int_0^{t/2} \sigma_x(\epsilon_x) z dz \quad (\text{Eq 2})$$

The strain shown in Eq 1 and 2,  $\epsilon_x$ , depends on  $z$ . Within the given assumptions, the circumfer-

**Fig. 2** Schematics of pure bending. (a) Configurations with coordinates defined. (b) Through-thickness stress distribution

ential strains ( $\epsilon_x$ ) are linearly related to the distance from the center of the sheet ( $z$ ) and inversely to the bend radius (of the center fiber of the body)  $R$ :

$$\epsilon_x \approx e_x = \frac{z}{R} \quad (\text{Eq 3})$$

where it is assumed that the true strain ( $\epsilon_x$ ) and the engineering strain ( $e_x$ ) are small enough to be used indistinguishably. As is shown explicitly, the bending moment can be calculated using Eq 2 and 3, along with a constitutive relationship between stress and strain.

Note: In order to simplify the notation, the subscript  $x$  is dropped from the terms  $\sigma_x$  and  $\epsilon_x$ , with the understanding that these represent the principal components of stress and strain normal to the beam or sheet cross section (as labeled in Fig. 2).

In order to compute the springback after bending, the moment per unit width of sheet,  $M/w$ , is removed from the sheet or beam while the material responds elastically. Because elastic stresses and strains can be superimposed, an alternative view of this operation is obtained by applying a moment ( $M$ ) to the stress-free body in the configuration of the bent beam or sheet. An isotropic linear elastic beam or sheet has a constitutive response of  $\sigma_x = E'\epsilon_x$ , where  $E'$  is the effective modulus for the beam (plane-stress case) or  $E' = E/(1-\nu^2)$ , where  $\nu$  is Poisson's ratio, for the sheet (plane-strain case).

For elastic recovery from an initially curved configuration (radius =  $R$ ) to a final configuration (radius =  $r$ ), the relationship for a body of general cross section is:

$$\frac{1}{R} - \frac{1}{r} = \frac{M}{E'I} \quad (\text{Eq 4})$$

where  $I$  is the moment of inertia of the cross section.

Note: The springback results for plane strain and plane stress do not differ greatly for most materials. Assuming that the bending moment is proportional to the operative flow stress for an isotropic, nonhardening, von Mises material, the plane-strain bending moment is  $2/\sqrt{3}$  (1.15) times the plane-stress moment. Assuming a typical Poisson's ratio of  $1/3$ , the plane-strain elastic modulus is 1.12 times the plane-stress (i.e., uniaxial tension) one. Thus, the differences between Eq 4 interpreted for plane stress or plane strain is only approximately 1.15 versus 1.12, or approximately a 3% differential. Elastic and plastic anisotropy may change this value.

Moments of inertia may be readily calculated for complex shapes by integration and have been tabulated for a variety of standard structural shapes (Ref 10). For the case of a rectangular cross section, which is assumed in the remainder of this article, the moment of inertia is taken as:

$$I = \frac{wt^3}{12} \quad (\text{Eq 5})$$

where  $t$  is the sheet thickness. Equation 4 may be rewritten for a rectangular cross section in a

per-width format as:

$$\frac{1}{R} - \frac{1}{r} = \frac{M}{E'I} = \frac{12M/w}{E't^3} \quad (\text{Eq 6})$$

which may be readily rewritten in the alternate form:

$$\frac{r}{R} = \left[ 1 - R \frac{M}{E'I} \right]^{-1} = \left[ 1 - R \frac{12M/w}{E't^3} \right]^{-1} \quad (\text{Eq 7})$$

The form  $\left[ \frac{1}{R} - \frac{1}{r} \right]$  is called springback in this article, while the second form,  $r/R$ , is called the springback ratio. In general, the springback is positive ( $r > R$ ), and the springback ratio is thus greater than unity. The relationship between the two measures is as Springback ratio =  $1/(1 - R \cdot \text{Springback})$ . For most applications, springback as defined previously is the quantity of interest. For small curvature changes, the shape change displacements are proportional to springback. The springback ratio is occasionally used with some analytical procedures, so a few results in this article are presented using it.

Note that a fractional error associated with the evaluation of springback may be quite different from the fractional error associated with the springback ratio, depending on how large the second term of Eq 7 is relative to 1. That is, when the second term is small, errors of  $R/r$  will appear to be small even though the fractional errors on moment can be significant.

Equations 6 and 7 represent the fundamental springback result for pure bending with the assumptions listed. To apply Eq 6, it is necessary to first choose the plane-stress or plane-strain approximation based on width with respect to bend radius and thickness. The bending moment is computed using Eq 2 and 3 and an explicit material stress-strain law (and known stress state). This approach is used to reproduce some classical springback results in the remainder of this section.

**Rigid, Perfectly Plastic Result.** The simplest springback result for pure bending makes use of a rigid (i.e., no elastic strains), perfectly plastic (no strain hardening) material model (Ref 4–6, 8, 11–13). Under these assumptions, the bending moment (and thus the springback) is independent of the original bend radius:

$$\frac{M}{w} = 2 \int_0^{t/2} \sigma'_0 z dz = \frac{\sigma'_0 t^2}{4} \quad (\text{rigid, perfectly plastic}) \quad (\text{Eq 8})$$

where  $\sigma'_0$  is the yield stress (also the flow stress) of the material in plane stress or plane strain. The springback, defined here, is obtained using Eq 4:

$$\frac{1}{R} - \frac{1}{r} = \frac{3\sigma'_0}{E't} \quad \text{or, alternatively,} \quad \frac{R}{r} = 1 - \frac{3\sigma'_0 R}{E't} \quad (\text{rigid, perfectly plastic}) \quad (\text{Eq 9})$$

This result is often sufficient for springback prediction, and it reveals the importance of the

principal material properties as they affect springback:

- Springback is proportional to strength/stiffness, that is,  $\sigma'_0/E$ .
- Springback is inversely proportional to sheet thickness.

More detailed analysis alters the exact form of these dependencies, but the conclusion remains the same: materials that are strong relative to their elastic modulus are more susceptible to large springback, as are thinner materials. Thus, aluminum sheet of comparable strength to a steel alloy exhibits springback approximately three times greater, because its elastic modulus is approximately  $1/3$  as large as that of steel.

**Elastic, Perfectly Plastic Result.** The first refinement of Eq 9 is by the inclusion of elastic, perfectly plastic bending behavior (Ref 14, 15). That is, there will be an elastic core near the neutral axis. The location of the elastic-plastic transition has a  $z$ -coordinate of  $z^*$ , which is found by setting the yield strain ( $\sigma'_0/E'$ ) equal to the bending strain ( $z/R$ ):

$$z^* = \begin{cases} \frac{R\sigma'_0}{E'} & \text{for } \frac{R\sigma'_0}{E'} \leq \frac{t}{2} \\ & (\text{elastic-plastic case}) \\ \frac{t}{2} & \text{for } \frac{R\sigma'_0}{E'} > \frac{t}{2} \\ & (\text{elastic only, no springback}) \end{cases} \quad (\text{Eq 10a})$$

$$(\text{Eq 10b})$$

Note that the extent of the elastic core is proportional to the bend radius (i.e., inversely proportional to curvature), proportional to the yield stress, and inversely proportional to the elastic modulus. Thus, inclusion of the elastic part of the material response becomes progressively more important for gentle bending of high-specific-strength materials. As is shown later, for typical sheet metal press forming, the bend radius is typically small enough that the elastic region may be neglected without significant loss of accuracy.

Evaluation of the required integral to obtain the moment for elastic-plastic cases may be conveniently split into two terms, the second identical to the rigid, perfectly plastic case outside of the elastic core:

$$\frac{M}{w} = 2 \int_0^{z^*} \frac{E'z}{R} z dz + 2 \int_{z^*}^{t/2} \sigma'_0 z dz \quad (\text{Eq 11})$$

$$= \frac{2E'z^{*3}}{3R} + \frac{\sigma'_0 t^2}{4} - \sigma'_0 z^{*2}$$

Substituting the relationship for the elastic-plastic location,  $z^*$  (Eq 10a), obtains the elastic-plastic moment and springback results:

$$\frac{M}{w} = \frac{\sigma'_0 t^2}{4} - \frac{\sigma'^3_0 R^2}{3E'^2} \quad (\text{elastic, perfectly plastic}) \quad (\text{Eq 12})$$

$$\frac{1}{R} - \frac{1}{r} = \frac{12M/w}{E't^3} = \frac{12}{E't^3} \left[ \frac{\sigma_0'^2 t^2}{4} - \frac{\sigma_0'^3 R^2}{3E'^2} \right] \quad (\text{elastic, perfectly plastic}) \quad (\text{Eq 13})$$

The springback equation may be rewritten in an alternate form presented by Gardiner (Ref 14) using Eq 7:

$$\frac{R}{r} = 1 - \frac{3\sigma_0' R}{E't} + \frac{4\sigma_0'^3 R^3}{E'^3 t^3} = 1 - 3x + 4x^3, \quad \text{where } x = \frac{\sigma_0' R}{E't} \quad (\text{Eq 14})$$

Note that the left side of Eq 14 is the reciprocal of the springback ratio as defined in this article. The error introduced by ignoring the elastic core in springback calculations may be evaluated by comparing Eq 9 and 13 or, equivalently, Eq 8 and 11. Table 1 presents  $R/t$  ratios where the moment error is limited to 1, 2, 5, and 10%. For a given desired level of accuracy, the  $R/t$  ratio is the largest one that can be safely considered.

Typical  $R/t$  ratios for automotive press forming lie in the range of 5 to 25, although many examples outside of that range may be found, particularly with general three-dimensional shapes that are not amenable to simple analysis. The results in Table 1 show that ignoring the elastic core leads to very small errors in this range for normal materials (aluminum alloys with a yield stress of 500 MPa, or 73 ksi, are seldom suitable for complex press forming).

**Rigid, Strain-Hardening Results.** In addition to the results presented previously, bending moments and springback relationships for strain-hardening material models have been presented in various forms, including the following selections:

- Empirical forms (Ref 16)
- Rigid, arbitrary hardening (Ref 8)
- Rigid, power-law hardening (Ref 3–7)
- Rigid, linear hardening (Ref 2)

Power-law hardening models are frequently used for sheet forming analysis. The hardening law, often attributed to Hollomon (Ref 17), may be written as follows, in uniaxial stress and other fixed stress- or strain-ratio forms:

$$\sigma = K\varepsilon^n \quad (\text{uniaxial stress}) \quad \text{or} \quad \sigma' = K'\varepsilon'^n \quad (\text{general stress state}) \quad (\text{Eq 15})$$

where  $K$  is the strength parameter,  $K'$  is the effective strength parameter,  $n$  is the strain-hardening index, and the primes indicate that the strains and stresses to be considered must take into account the stress-strain state and the form of the yield function (anisotropic, quadratic, etc.). (Because elasticity is ignored,  $\varepsilon$  is the total strain, equal to the plastic strain.) Typical results for such hardening may be summarized as (Ref 6):

$$\frac{M}{w} = \left( \frac{2}{n+2} \right) \frac{K'}{R^n} \left( \frac{t}{2} \right)^{n+2} \quad (\text{Eq 16})$$

$$\frac{1}{R} - \frac{1}{r} = \left( \frac{6}{n+2} \right) \frac{K'}{E't} \left( \frac{t}{2R} \right)^n \frac{1}{t} \quad (\text{Eq 17})$$

**Elastic-Plastic Result.** Bending moments and springback relationships for elastoplastic, strain-hardening material models have also been presented in various forms, including:

- Elastic, power-law hardening (Ref 18, 19)
- Rigid, linear hardening (Ref 18)

In order to assess the importance of strain hardening in pure bending results, moment and springback formulas were derived based on a hardening law of the following form:

$$\sigma = \sigma_0 + K\varepsilon_p^n \quad (\text{uniaxial stress}) \quad \text{or} \quad \sigma = \sigma_0' + K'\varepsilon_p'^n \quad (\text{general case}) \quad (\text{Eq 18})$$

For the plane-stress case,  $\varepsilon_p$  signifies the approximate plastic strain, that is, the total strain less the elastic yield strain:

$$\varepsilon_p = \varepsilon - \varepsilon_e \approx \frac{z - z^*}{R} \quad (\text{Eq 19})$$

The second equality of Eq 19 is approximate because the elastic strain ( $\varepsilon_e$ ) is treated as a constant corresponding to the value at first yield, rather than as evolving with hardening. This approximation, adopted for simplicity, has little effect on the result.

The moment consists of three terms, the first two identical to the elastic, perfectly plastic result, that is, Eq 12 (with yield stress,  $\sigma_0$ ), and the third an integral corresponding to the additional moment caused by the hardening beyond the yield stress. This third term may be evaluated as:

$$\frac{\Delta M}{w} = 2 \int_{z^*}^{t/2} K\varepsilon_p^n dz = \frac{2K}{R^n} \int_{z^*}^{t/2} (z - z^*)^n z dz \quad (\text{uniaxial}) \quad (\text{Eq 20})$$

where, as before,  $z^* = R\sigma_0/E$ . Equation 20 may be evaluated to obtain the explicit form of the incremental moment:

$$\frac{\Delta M}{w} = \frac{2K}{R^n(n+2)} \left( \frac{t}{2} - z^* \right)^{n+2} + \frac{2Kz^*}{R^n(n+1)} \left( \frac{t}{2} - z^* \right)^{n+1} \quad (\text{Eq 21})$$

The full moment for the elastic, hardening plastic case is thus:

$$\frac{M}{w} = \frac{\sigma_0 t^2}{4} - \frac{\sigma_0^3 R^2}{3E^2} + \frac{2K}{R^n(n+2)} \left( \frac{t}{2} - z^* \right)^{n+2} + \frac{2Kz^*}{R^n(n+1)} \left( \frac{t}{2} - z^* \right)^{n+1} \quad (\text{Eq 22})$$

and the springback is then:

$$\frac{1}{R} - \frac{1}{r} = \frac{12M/w}{E't^3} \quad (\text{Eq 23})$$

where  $M$  is given by Eq 22.

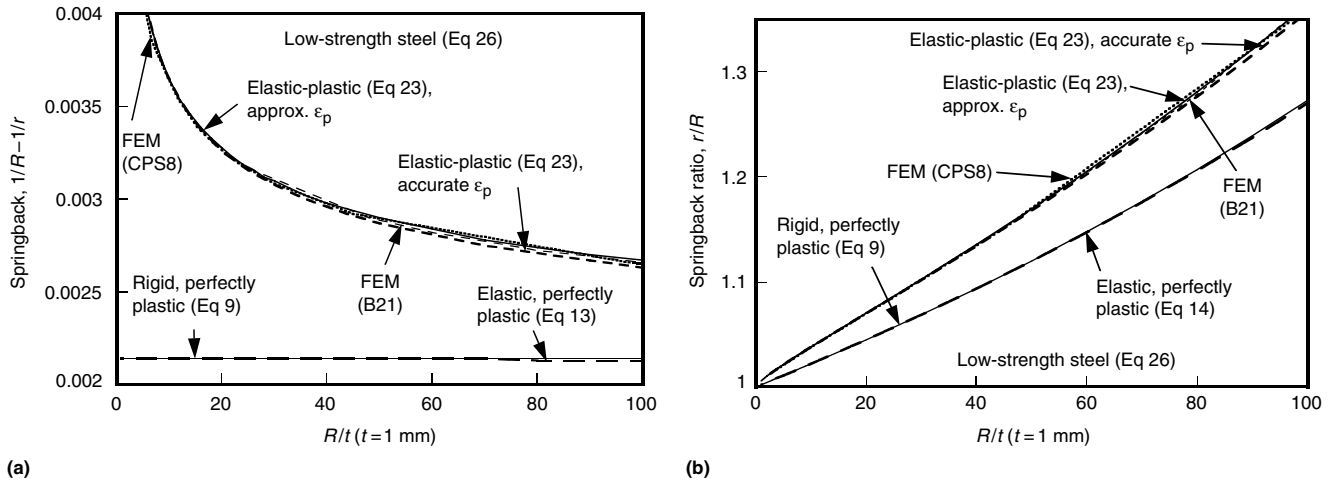

Springback based on Eq 23 is compared in Fig. 3 with springback computed analytically using elastic, perfectly plastic material behavior (Eq 13), rigid, perfectly plastic material behavior (Eq 9), and elastic-plastic finite element (FE) simulations of four-point bending (Fig. 4). (Finite element simulations are introduced later in this article, but are included here for completeness. The FE results presented in Fig. 3 were verified by refining meshes and number of integration points until no significant changes were observed.) The FE simulations make use of either plane-stress quadratic solid elements (labeled CPS8) or plane-stress beam elements with shear terms (labeled B21). The element labels correspond to the ABAQUS (Ref 20) elements used.

For purposes of Fig. 3 and subsequent use in this article, two material models corresponding to ratios of extremes of yield stress ( $\sigma_y$ ) to Young's modulus for typical forming materials were defined based on Eq 18. The soft material, low-strength steel, is based on properties appearing in the literature (Ref 21) for interstitial-free steel: yield stress is 150 MPa (22 ksi), ultimate tensile strength is 310 MPa (45 ksi), and uniform elongation is 28.5%. The hard material, high-strength aluminum, is based on the properties appearing in the literature (Ref 22) for 7075-T6: yield stress is 500 MPa (73 ksi), ultimate tensile strength is 572 MPa (83 ksi), and uniform elongation is 11%.

Parameters of Eq 18 can be determined from the yield stress, ultimate tensile strength, and uniform elongation by noting two conditions: 1) the engineering stress at the uniform elongation is equal to the ultimate tensile strength ( $\sigma_{UTS}$ ), and 2) the derivative of the true stress/true plastic strain equation is equal to the true stress at the uniform elongation ( $\sigma_y$ ) (or corresponding plastic true strain,  $\varepsilon_p^y$ ). Use of these two conditions, and associating  $\sigma_0$  of Eq 18 with the yield stress,  $\sigma_y$ , allows determination of the parameters of Eq 18

**Table 1** Maximum ratios of bending radius to thickness ( $R/t$ ) for specified moment errors by neglecting the elastic core in bending (perfectly plastic)

Material	Yield stress		Young's modulus		Maximum $R/t$ for moment error of:			
	MPa	ksi	GPa	10 <sup>6</sup> psi	1%	2%	5%	10%
Low-strength steel	150	22	210	30	85	120	190	270
Low-strength aluminum	150	22	70	10	28	40	64	90
High-strength steel	500	73	210	30	26	36	57	81
High-strength aluminum	500	73	70	10	9	12	19	27

**Fig. 3** Effect of various approximations (Eq 9, 13, 14, 23, and 26) on simulated springback quantities. (a) Springback. (b) Springback ratio.  $R$ , radius of primary bending curvature;  $r$ , radius of curvature after springback;  $\epsilon_p$ , plastic strain; FEM, finite element modeling;  $t$ , thickness. CPS8 and B21 are ABAQUS 6.2 element designations. Source: Ref 20

**Fig. 4** Finite element modeling (FEM) mesh (CPS8 plane-stress solid elements shown) and tools for simulation of pure bending.  $M$ , bending moment;  $P$ , applied load in four-point bend FEM;  $r_d$ , tool radius in four-point bend FEM;  $L$ , half-sample length. Source: Ref 20

as follows:

$$n = \frac{\sigma_f}{\sigma_f - \sigma_y} \epsilon_f^p \quad (\text{Eq 24})$$

$$K = \frac{\sigma_f - \sigma_y}{(\epsilon_f^p)^n} \quad (\text{Eq 25})$$

For the two chosen materials, explicit elastic-plastic constitutive equations are:

Low-strength steel:

$$\sigma = 150 \text{ MPa} + 425 \text{ MPa} \epsilon_p^{0.4}, E = 210 \text{ GPa} \quad (\text{Eq 26})$$

High-strength aluminum:

$$\sigma = 500 \text{ MPa} + 400 \text{ MPa} \epsilon_p^{0.45}, E = 70 \text{ GPa} \quad (\text{Eq 27})$$

As illustrated in Fig. 3(a) neglecting strain hardening leads to large errors in springback throughout the range of  $R/t$  tested, varying from

approximately 20 to 50%. (The smaller fractional error for springback ratio is illustrated in Fig. 3b.) For pure bending, Eq 23 is in good agreement with the FE results, whether or not the strain distribution through the thickness of the sheet is approximated.

### Approximations in Classical Bending Theory

In this section, the assumptions introduced previously are discussed and, in some cases, evaluated semiquantitatively. As is shown throughout this article, the most important aspects for accuracy in springback prediction for typical sheet forming operations ( $R/t$  assumed to be in the range of 5 to 25) involve:

- Sheet tension (most critical aspect, presented in the next section)

- The hardening law (discussed in the previous and last sections)
- Presence of anticlastic curvature (this section and the last)

The basic assumptions of the previous section for pure bending have fairly small errors associated with them. However, these errors can grow when elastic-plastic laws are considered and when bending and unbending occur. It is useful to consider first the effect of the various approximations made within the foregoing pure-bending analysis.

**Assumption 1: Plane Sections Remain Planar.** For bending and bending under tension, this assumption is very nearly satisfied under most circumstances. For  $R/t \geq 5$ , shell finite elements (which incorporate this assumption, among others) agree well with full solid elements, which allow general deformation patterns (see later section of this article). Therefore, for  $R/t > 5$ , the assumption degrades the accuracy little. Another indicator is the accuracy of more complicated closed-form solutions for pure bending. These solutions (Ref 4, 5, 19, 23) retain the planar section assumption but allow through-thickness stresses to develop. These solutions are in good agreement with experiments for small  $R/t$ , thus indicating again that the assumption of plane sections has little effect on pure bending over a wide range of  $R/t$ .

There are two circumstances where this assumption may be significantly violated: when the frictional stress of sliding on the inner surface of the part is significant relative to bending and stretching forces, and when the hardening law is such that instabilities can occur (assumption 4 in this section). For pure bending and bending under tension (i.e., without frictional contact), the assumption of plane sections remaining plane is reasonable for most situations, probably down to  $R/t$  ratios as small as 1.

**Assumption 2: No Change in Sheet Thickness.** This assumption is related intimately with pure bending, for which it is very accurate, even to small  $R/t$  ratios. Thick shell results (Ref 23, 24) show this directly, although for  $R/t$  ratios less than 1, some thickness changes can occur (Ref 25). The use of the phrase “thick shell” in this article refers to a relaxation of some thin-shell approximations. This is distinct from the specialized use of this phrase in the mechanics literature to refer to a particular, systematic development of the kinematics of shell theory. For bending under tension, as presented in the next section, the thickness change is marked.

**Assumption 3: Two-Dimensional Geometry, Either Plane Strain or Plane Stress in Width Direction.** This is not a good assumption for many bending operations. As illustrated in Fig. 5, as bending occurs in the principal axis, a curvature develops across the width of the specimen. The effect is well known (Ref 26, 27).

The origin of this anticlastic curvature is easily understood: the principal bending causes lengthening of fibers above the neutral axis and shortening of those below it. For lengthened fibers there are Poisson contractions in the width and thickness directions, while for the shortened fibers there are expansions. Across the entire thickness, for pure bending, these very nearly balance each other, hence assumption 2 (no change in sheet thickness) is very accurate under most circumstances.

When the width changes are considered, the tendency to develop a secondary curvature is clear. The outer fibers tend to contract laterally and the inner ones to expand, so a concave-up curvature is favored. For very wide geometries (relative to thickness and bend radius), the plane-strain assumption becomes the limiting case (although there will always be some anticlastic curvature near the sheet edges). For narrow geometries, the anticlastic curvature is unimpeded by shear terms, and the cross section adopts a circular shape with radius of curvature  $R_a = v/R$  (Ref 9). The plane-stress assumption is the limiting case when there are no stresses resisting the adoption of this shape.

For pure-elastic bending, the shape of the cross section has been found analytically (Ref 28), and a literature review of the subject has appeared (Ref 29). In spite of the limited accuracy of the result for small  $R/t$  (the inaccuracy arises by considering the bent configuration to be parabolic), the results are illuminating for typical sheet-forming cases.

The most important result is that the configuration of the bent part is determined by a single dimensionless parameter ( $\beta$ ) describing the normalized width ( $w$ ) of the specimen, sometimes called Searle's parameter (Ref 30, 31):

$$\beta = \frac{w^2}{Rt} = \frac{w}{R} \cdot \frac{w}{t} \quad (\text{Searle's parameter})$$

(Eq 28)

along with the Poisson's ratio,  $v$ . The actual shape of the cross section for various values of  $\beta$  is illustrated in Fig. 6, where the bend radii

are also shown assuming a fixed width of 50 and unit thickness of 1. The results in Fig. 6 correspond to the analytic solution as follows, where  $C_1$  and  $C_2$  are numerical constants:

$$\left(\frac{z}{t}\right) = C_1 \cosh\left(\frac{y\alpha}{w}\right) \cos\left(\frac{y\alpha}{w}\right) + C_2 \sinh\left(\frac{y\alpha}{w}\right) \sin\left(\frac{y\alpha}{w}\right) \quad (\text{Eq 29})$$

$$\text{where } C_{2,1} = \frac{v}{\sqrt{3(1-v^2)}} \times \frac{\sinh\left(\frac{\alpha}{2}\right) \cos\left(\frac{\alpha}{2}\right) \pm \cosh\left(\frac{\alpha}{2}\right) \sin\left(\frac{\alpha}{2}\right)}{\sinh(\alpha) + \sin(\alpha)}$$

with  $\alpha = \sqrt[4]{3(1-v^2)}\sqrt{\beta}$ .

**Fig. 5** Anticlastic surface with two orthogonal curvatures.  $R$ , radius of primary bending curvature;  $R_a$ , radius of anticlastic curvature

**Fig. 6** Shape of cross sections for various values of Searle's parameter,  $\beta = (w^2/Rt)$ .  $z$ , thickness coordinate;  $t$ , sheet thickness;  $y$ , width coordinate;  $w$ , sheet width;  $v$ , Poisson's ratio;  $R$ , radius of primary bending curvature;  $\beta$ , Searle's parameter

For  $\beta$  greater than approximately 100, the edge regions look similar and the center region is essentially flat, thus implying that plane-strain conditions are accurate except at the local edge regions. For small  $\beta$ , the cross-sectional shape is essentially circular, which implies that the stresses resisting this curvature may be safely ignored (i.e., plane stress).

The transition from the plane-stress limit to the plane-strain limit is a smooth function of  $\beta$ , as shown in Fig. 7. The limiting values of  $\beta$  for specified errors of the effective moment of inertia are shown in Table 2.

For springback application, the most important effect of anticlastic curvature is two-fold: on the bending moment-curvature relationship, and on the elastic unloading response. The latter will depend greatly on the degree to which the anticlastic shape persists, that is, how much of the anticlastic shape is retained after unloading. For the case of pure-elastic bending and unloading, there is no difference in springback, that is, zero springback, for cases with or without anticlastic effects. Persistent anticlastic curvature is particularly important for the typical sheet-forming case bending and unbending, as is discussed in the last section of this article. For parts curved in three dimensions, the anticlastic curvature may manifest itself as wrinkling, twisting, or generalized distortion. See, for example, the wrinkled area of the S-rail (Fig. 1a).

**Assumption 4: Constant Curvature (i.e., No Instability in Shape).** This is closely related to assumption 1. For bending and bending under tension, instabilities can occur because of shear

**Fig. 7** The transition from the plane stress to plane strain, as a function of  $\beta = (w^2/Rt)$ .  $\phi$ , anticlastic factor;  $E$ , Young's modulus;  $I$ , moment of inertia;  $M$ , bending moment;  $R$ , radius of primary bending curvature;  $w$ , width;  $t$ , thickness;  $v$ , Poisson's ratio

**Table 2** Limiting values of  $\beta$  ( $w^2/Rt$ ) for specified accuracy limits using plane-stress or plane-strain bending formulas

$\beta$ limit	Limiting value of $\beta$ for an accuracy limit of:			
	1%	2%	5%	10%
Plane stress ( $\beta <$ )	2	3	5	34
Plane strain ( $\beta >$ )	170	42	7	2

banding, for example. These instabilities are expected to be of a similar magnitude and importance and in the same range of strains as for tension or compression. Therefore, when a stable hardening law is obtained (without serrated yielding, Lüder's banding, or yield-point phenomenon), bending may be assumed to behave similarly.

**Assumptions 5, 6, and 7: No Stress in the Radial, or Through-Thickness, Direction. The Neutral (Stress-Free) Axis is the Center Fiber and is the Zero-Extension Fiber. No Distinction between Engineering and True Strain.** These three assumptions are closely related and may be considered together naturally. To consider these effects profitably, it is simpler to ignore, for the moment, anticlastic curvature. Each of these assumptions is closely related to the  $R/t$  ratio to which a flat beam or plate is bent initially. The effect of bending to  $R/t$  less than approximately 5 produces significant through-thickness stresses in the interior of the body and causes the stress-free axis to vary significantly from the zero-extension fiber. Bending to small  $R/t$  also produces large strains at the outer fibers, thus making the distinction between true and engineering strains more significant (Ref 32).

The last of these effects is the simplest to quantify. In order to do so, consider the elastic-plastic result of Eq 20, but this time evaluate the strains in terms of true strains, that is:

$$\varepsilon_p = \varepsilon - \varepsilon_e \approx \ln\left(1 + \frac{z}{R}\right) - \ln\left(1 + \frac{z^*}{R}\right) \quad (\text{Eq 30})$$

Note that again the additional elastic strain that accrues with strain hardening after the elastic-plastic transition point has been ignored. This allows Eq 20 to be rewritten as:

$$\begin{aligned} \frac{M'}{w} &= 2 \int_{z^*}^{t/2} K \varepsilon_p^n z dz \\ &= 2K \int_{z^*}^{t/2} \left[ \ln\left(1 + \frac{z}{R}\right) - \ln\left(1 + \frac{z^*}{R}\right) \right]^n z dz \end{aligned} \quad (\text{Eq 31})$$

where, except for the use of true strains, all the other assumptions remain the same. Evaluation of Eq 31 shows that the error on  $M$  introduced by neglecting true strain is 3.8% for  $R/t = 1$  and less than 0.64% for  $R/t \geq 5$ . Therefore, other assumptions introduce larger errors than this one. (Note that a true kinematical description of bending, whether finite or infinitesimal, is not used for any derivations here. Only the evaluation of strain differs.)

The remaining assumptions related to small  $R/t$  can be assessed by the thick-shell solutions for rigid, perfectly plastic behavior presented first by Hill (Ref 33) and later in simplified forms (Ref 4, 5) and less restrictive forms for elastic-plastic cases (Ref 19). The conditions found to hold even during bending to small  $R/t$  are plane strain (assumed) and no thickness change.

Maintaining these conditions during bending to small  $R/t$  requires consideration of the quadratic terms in the value of the circular arc. The results show that significant through-thickness stresses develop and the stress-free fiber is no longer the zero-extension fiber. The details of the derivations may be found in the references provided, but the general result is that the total true strain for the more precise form is given by:

$$\varepsilon = \ln \left[ 1 + \left( \frac{t}{2R} \right)^2 + \left( \frac{2z}{R} \right) \right]^{1/2} \quad (\text{Eq 32})$$

and the plastic problem must be solved incrementally in order to determine the stress distribution throughout the plastic deformation.

Figure 8 illustrates the relative magnitude of the various approximations for pure bending. The deviations are quite small for the pure bending case.

**Assumption 8: Isotropic, Homogeneous Material Behavior.** For fixed stress state (plane stress, for example) or strain state (plane strain, for example), the introduction of anisotropy, elastic and plastic, makes no fundamental change in the treatment of two-dimensional bending and springback results. While an extensive treatment of anisotropy is beyond the scope of this article, a simple result can illustrate the general procedure. For more complicated cases, FE analysis is usually required, and FE programs usually have capabilities incorporating material anisotropy.

It is important to note that anisotropy does not affect the basic equations for the simple bending case. For the plastic bending, the relationship between tensile strain at a given fiber and the fiber location (Eq 3) is independent of anisotropy. The relationship between the normal principal stress ( $\sigma_x$ ) and the bending moment (Eq 2) is also unchanged. For the elastic unloading, the relationship governing the change of curvature remains the same, except that the modulus is the effective one relating tensile strain ( $\varepsilon_x$ ) to normal principal stress ( $\sigma_x$ ), taking anisotropy into account.

The role of anisotropy may be reflected sufficiently in a generalized elastic relationship:

$$\sigma_x = E' \varepsilon_x = f_E E \varepsilon_x \quad (\text{elastic}) \quad (\text{Eq 33})$$

where  $E'$  is the effective modulus for the given strain-stress state, and  $f_E$  is a constant factor equal to  $E'/E$ .

For the plastic relationship, it should be noted that strain hardening is usually specified in terms of effective strain ( $\bar{\varepsilon}$ ) and stress ( $\bar{\sigma}$ ) based on a tensile test:

$$\bar{\sigma} = f(\bar{\varepsilon}) \text{ for example } \bar{\sigma} = K \bar{\varepsilon}^n \quad (\text{Eq 34})$$

Using similar notation, the constant factor reflecting plastic anisotropy and stress-strain state may be defined (Ref 34, 35):

$$\bar{\varepsilon} = f_\varepsilon \varepsilon_x, \quad \bar{\sigma} = f_\sigma \sigma_x \quad (\text{Eq 35})$$

For any fixed anisotropy and strain-stress state, the values of  $f_E$ ,  $f_\sigma$ , and  $f_\varepsilon$  may be found and

used to complete the basic bending and springback equation, such as Eq 2 to 4.

As an example, consider a sheet with normal plastic anisotropy according to Hill's quadratic yield function (Ref 33). The factors  $f_\varepsilon$  and  $f_\sigma$  can be derived for a given plastic anisotropy parameter (Ref 34),  $\bar{r}$ , as:

$$f_\varepsilon = \frac{1 + \bar{r}}{\sqrt{1 + 2\bar{r}}}, \quad f_\sigma = \frac{\sqrt{1 + 2\bar{r}}}{1 + \bar{r}} \quad (\text{Eq 36})$$

The necessary strain-hardening relationship,  $\sigma_x(\varepsilon_x)$  in Eq 2, may then be found in terms of a measured uniaxial hardening law,  $\bar{\sigma} = f(\bar{\varepsilon})$ :

$$\sigma_x(\varepsilon_x) = \frac{\bar{\sigma}}{f_\sigma} = \frac{1}{f_\sigma} f(\bar{\varepsilon}) = \frac{1}{f_\sigma} f(f_\varepsilon \varepsilon_x) = \frac{1}{f_\sigma} f\left(f_\varepsilon \frac{z}{R}\right) \quad (\text{Eq 37})$$

The substitution may be illustrated conveniently by taking a particular hardening law, say  $\bar{\sigma} = K \bar{\varepsilon}^n$ :

$$\begin{aligned} \sigma_x &= \frac{K}{f_\sigma} \left(f_\varepsilon \frac{z}{R}\right)^n = \frac{K(1 + \bar{r})}{\sqrt{1 + 2\bar{r}}} \left[ \frac{1 + \bar{r}}{\sqrt{1 + 2\bar{r}}} \frac{z}{R} \right]^n \\ &= \frac{(1 + \bar{r})^{n+1}}{(1 + 2\bar{r})^{\frac{n+1}{2}}} K \left(\frac{z}{R}\right)^n = K' \left(\frac{z}{R}\right)^n \end{aligned} \quad (\text{Eq 38})$$

where  $K'$  represents all of the needed changes. The same procedure may be applied to any strain state, tensile hardening law, and fixed plastic anisotropy.

It should also be noted that an assumption of symmetric yielding in tension and compression has been made. For as-received sheet material, this is usually a reasonably accurate picture of the stress-strain behavior. However, as is discussed in the section, "Applied Analysis of Simple Forming Operations" in this article the hardening behavior can become complex in reverse bending, which is common in many sheet-forming situations. Under these conditions, the Bauschinger effect on strain reversal must be considered. (Strictly speaking, some strain increment reversal can take place in single bending, because the neutral surfaces move relative to the midplane. This effect appears not to have been analyzed and is likely very small in practical cases.)

**Fig. 8** Comparison of various approximations for elastoplastic pure bending

Finally, initial material properties are assumed to be the same at each point in the body.

**Assumption 9: Springback Occurs Elastically.** For all pure bending and nearly all bending under tension cases, this is very accurate. However, contrary to assertions in the literature (Ref 36), elastic-plastic springback can occur for bending under high sheet tensions (approaching and beyond the yield stress) (Ref 37–40) and when the material behavior is time-dependent (i.e., via creep or anelasticity) (Ref 41, 42). A few examples of such situations are mentioned in the section “Applied Analysis of Simple Forming Operations” in this article.

For most situations, these effects can be ignored without greatly affecting the result. However, it should be noted that unloading itself may involve inelastic effects (Ref 43) that produce changes in the observed modulus (Ref 44). There has been no clear approach on how such effects can be incorporated in springback analysis except for adjusting the effective elastic modulus.

## Bending with Tension

The effect of superimposed tension during bending plays a dominant role in determining springback, as is demonstrated with simple analyses. Nearly all sheet-forming operations involve at least some sheet tension, whether introduced by remote sections of the part undergoing deformation, local friction conditions, or the intentional action of a draw bead or other restraint. Increasing sheet tension to reduce springback and its variability has been the principal industrial solution to the problem of inadequate shape fixability.

Analyses similar to those for pure bending can be carried out by relaxing just one of the assumptions listed in the first section, namely the sixth one, that is, that the neutral (stress-free) axis is the center fiber and is the zero-extension fiber. The sheet thickness may change substantially if the tension is high during bending (Ref 45) (and particularly for bending and unbending, which is not considered until the next section), but this effect is often ignored for simplicity. (For FE simulation, in the next section, shell elements usually assume zero thickness change in one time step, but the thickness is updated at the end of each step.)

Springback solutions for bending with tension have been presented with various levels of complexity, including elastic, perfectly plastic (Ref 6–13); elastic, power-law hardening (Ref 18, 19, 46–48); elastic, linear hardening (Ref 18, 49, 50); and rigid, power-law hardening (Ref 51–54). Extension to more complex cases includes: biaxially loaded plates (Ref 36), bending to small radii with tension (Ref 19), the effect on nonsimultaneous tension and bending (i.e., pre-bending or postbending) (Ref 51), taking into account section changes in narrow strips (Ref 7), the role of nonuniform deformation (Ref 55),

results for laminated sheets (Ref 56), and the effect on formability and residual-stress distribution (Ref 57).

**Elastic, Perfectly Plastic Result.** The simplest elastic, perfectly plastic solution for bending with tension is sufficient to reveal the dominating importance of tension relative to other variables. Initially considering the thickness constant, the strain distribution through the sheet thickness is a simple superposition of a tensile or membrane strain ( $\epsilon_m$ ) and the bending strain ( $\epsilon_b$ ) as before:

$$\epsilon = \epsilon_m + \epsilon_b = \epsilon_m + \frac{z}{R} \quad (\text{Eq 39})$$

At the neutral axis (assumed to be the zero-extension axis), located at  $z_0$ , the strain is zero, so an expression relating the membrane strain and the neutral axis location is obtained:

$$\epsilon_m = -\frac{z_0}{R} \quad (\text{Eq 40})$$

The stress distribution is similar to the one shown in Fig. 9, which may be integrated to obtain the overall sheet tension,  $T$ , (per unit width,  $w$ ) operating:

$$\frac{T}{w} = \int_{-t/2}^{t/2} \sigma'_0 dz = \int_{-t/2}^{z_0} -\sigma'_0 dz + \int_{z_0}^{t/2} \sigma'_0 dz = -2z_0\sigma'_0 \quad (\text{Eq 41})$$

It is convenient to rewrite Eq 41 in terms of normalized quantities:  $z_0/t$ , the fractional location of the neutral axis, and  $\bar{T}$ , the average sheet tension stress ( $T$  divided by sheet width and thickness) divided by stress to yield the sheet ( $\sigma'_0$ ), yielding  $\left(\bar{T} = \frac{T}{wt\sigma'_0}\right)$ . In terms of these reduced variables, Eq 41 becomes:

$$\left(\frac{z_0}{t}\right) = -\frac{\bar{T}}{2} \quad (\text{Eq 42})$$

With the location of the neutral axis known explicitly in terms of the sheet tension, the moment may be evaluated in closed form:

$$\frac{M}{w} = \frac{\sigma'_0 t^2}{4} [1 - \bar{T}^2], \text{ or} \quad (\text{Eq 43})$$

$$\left(\frac{M/w}{t^2}\right) = \frac{\sigma'_0}{4} [1 - \bar{T}^2] \quad (\text{Eq 44})$$

where Eq 44 emphasizes the proper normalization with thickness. The springback may then be presented in standard and normalized closed forms with the help of Eq 6 and 14 as:

$$\frac{1}{R} - \frac{1}{r} = \frac{12M/w}{E't^3} = \frac{3\sigma'_0}{E't} [1 - \bar{T}^2] \quad (\text{Eq 45})$$

$$\frac{R}{r} = 1 - \frac{3\sigma'_0}{E'} \left(\frac{R}{t}\right) [1 - \bar{T}^2] \quad (\text{Eq 46})$$

Equations 45 and 46 ignore the thickness change that occurs by the action of the sheet

**Fig. 9** Schematic of the stress distribution in a beam or sheet, bent to radius  $R$ , with definition of various coordinates used in the analysis of springback

tension; that is, final thickness  $t$  is assumed to be equal to original thickness  $t_0$ . The expressions may be approximately corrected for thickness changes by assuming that the final thickness is related to the original thickness such that the volume is maintained using the membrane strain (a linear approximation for the definition of strain is used for simplicity); that is:

$$\frac{t-t_0}{t_0} = -\varepsilon_m = \frac{z_0}{R} = -\frac{t\bar{T}}{2R} \quad (\text{Eq 47})$$

where  $t_0$  is the initial thickness, and the final thickness,  $t$ , is given by:

$$t = \left( \frac{1}{t_0} + \frac{\bar{T}}{2R} \right)^{-1} \quad \text{or} \quad \frac{t}{R} = \frac{1}{(R/t_0) + \bar{T}/2} \quad (\text{Eq 48})$$

which gives an expression for the final thickness that may be substituted into Eq 45 and 46 to obtain thickness-corrected versions:

$$\frac{1}{R} - \frac{1}{r} = \frac{12M/w}{E't^3} = \frac{3\sigma'_0}{E'R} \left( \frac{R}{t_0} + \frac{\bar{T}}{2} \right) (1 - \bar{T}^2) \quad (\text{Eq 49})$$

$$\frac{R}{r} = 1 - \frac{RM/w}{E'I} = 1 - \frac{3\sigma'_0}{E'I} \left( \frac{R}{t_0} + \frac{\bar{T}}{2} \right) (1 - \bar{T}^2) \quad (\text{Eq 50})$$

The results represented by Eq 46 and 50 are shown graphically in Fig. 10. As can be seen readily, the application of sheet tension substantially reduces springback. For the perfectly plastic case, springback disappears when the normalized sheet tension approaches unity, that is, when the average tensile stress approaches the appropriate yield stress. By setting  $\bar{T} = 0$ , the pure bending result (Eq 9, for example) is obtained.

**Rigid, Power-Law Hardening Result.** Using the approach followed previously, the springback predicted for bending with tension can be derived. Unfortunately, it is not in a form as convenient as for the perfectly plastic case. The

only additional complexity is that  $t$  cannot be found explicitly in terms of  $\bar{T}$ , so that  $M$  cannot be written as an explicit function of  $\bar{T}$ . It is simplest to proceed by choosing  $R/t_0$  and  $z_0/t_0$  as independent variables, then evaluating the sheet tension, bending moment, and thus springback. In this way, springback may be obtained as a function of sheet tension but not in a closed equation form.

A power-law hardening law with a yield stress as in Eq 15 is adopted, and similar assumptions to the ones mentioned previously are made. Because total strain is represented by Eq 39, the stress throughout the sheet thickness is:

$$\sigma = \begin{cases} \sigma'_0 + K'\varepsilon^n, & \varepsilon > 0 \quad \text{or} \\ \sigma'_0 + K'\left(\frac{z-z_0}{R}\right)^n, & z > z_0 \\ -(\sigma'_0 + K'|\varepsilon|^n), & \varepsilon < 0 \quad \text{or} \\ -\sigma'_0 - K'\left(\frac{z_0-z}{R}\right)^n, & z < z_0 \end{cases} \quad (\text{Eq 51})$$

where, as was previously done, the plastic strain is approximated by the total strain (evaluated using the linear, small-strain definition) minus the elastic strain at yield. The normalized sheet tension and bending moment increment (beyond perfectly plastic) may then be obtained as:

$$\begin{aligned} \bar{T} &= -2\left(\frac{z_0}{t}\right) + \frac{K'}{(n+1)\sigma'_0} \left(\frac{t}{R}\right)^n \\ &\times \left[ \left(\frac{1}{2} - \frac{z_0}{t}\right)^{n+1} - \left(\frac{1}{2} + \frac{z_0}{t}\right)^{n+1} \right] \end{aligned} \quad (\text{Eq 52})$$

$$\begin{aligned} \frac{\Delta M/w}{t^2} &= K \left(\frac{t}{R}\right)^n \left[ \frac{(0.5 + \frac{z_0}{t})^{n+2} + (0.5 - \frac{z_0}{t})^{n+2}}{n+2} \right. \\ &\quad \left. - \left(\frac{z_0}{t}\right) \times \frac{(0.5 - \frac{z_0}{t})^{n+1} + (0.5 + \frac{z_0}{t})^{n+1}}{n+1} \right] \end{aligned} \quad (\text{Eq 53})$$

where the current thickness must be evaluated in terms of  $z_0$  using either the true-strain definition

or the small-strain approximation:

$$\frac{t}{t_0} = \exp\left(\frac{z_0}{R}\right) \approx \left(1 + \frac{z_0}{R}\right) \quad (\text{Eq 54})$$

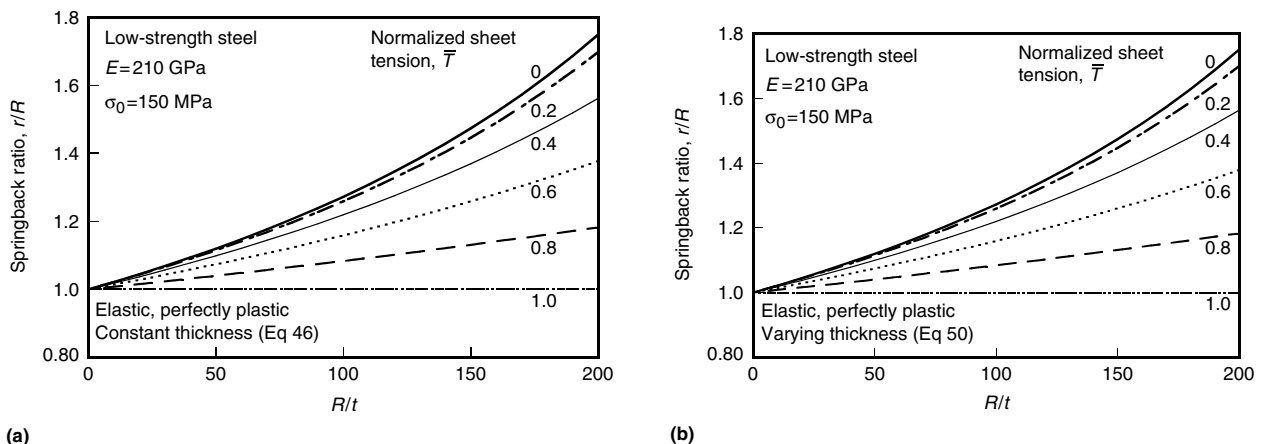

Equation 53 represents the additional bending moment caused by strain hardening that must be added to the perfectly plastic moment (Eq 43). The springback ratio is then evaluated using Eq 7. The final springback ratio is shown in Fig. 11.

**Corrections to the Simple Power-Law Hardening Result.** It is possible to obtain more accurate solutions for this case; however, the equations become rather bulky, will usually require numerical evaluation of integrals, and they will differ for each kind of hardening law considered. (In the truly arbitrary case, a numerical integration can be carried out to obtain the appropriate solution.) Nonetheless, it is useful to illustrate the additional terms that can be considered for completeness and estimation of importance (still adopting assumptions 1 and 3).

For large  $\bar{T}$  or small  $R/t$  (i.e., large strain), the true-strain definition should be used such that the strains no longer vary linearly through the thickness, except approximately:

$$\begin{aligned} \varepsilon &= \varepsilon_m + \varepsilon_b = \ln\left(1 - \frac{z_0}{R}\right) + \ln\left(1 + \frac{z}{R}\right) \\ &= \ln\left(1 - \frac{z_0}{R}\right) \left(1 + \frac{z}{R}\right) \\ &= \ln\left(1 - \frac{z_0}{R} + \frac{z}{R} - \frac{z_0 z}{R^2}\right) \\ &\cong -\frac{z_0}{R} + \frac{z}{R} \left(1 - \frac{z_0}{R}\right) \end{aligned} \quad (\text{Eq 55})$$

Inclusion of the large strain formula via Eq 55 will usually require numerical evaluation of the integrals to obtain  $\bar{T}$  and  $M$ . Furthermore, bending to large curvatures ( $R/t$  less than approximately 5) introduces errors in the other approximations that are more significant than the small strain form (see the section "Approximations in Classical Bending Theory" in this article). Forms equivalent to the last approximate

**Fig. 10** Effect of sheet tension on springback for an elastic, perfectly plastic constitutive equation for low-strength steel. (a) Constant thickness. (b) Changing thickness.  $r$ , radius of curvature after springback;  $R$ , radius of primary bending curvature;  $t$ , sheet thickness;  $E$ , Young's modulus;  $\sigma_0$ , initial yield stress

one shown in Eq 55 have been used in the derivations already presented.

Figure 12 shows that the use of true or engineering strain ( $\epsilon_t$ ) has little effect on either the thin-shell or thick-shell solutions. Even at  $R/t = 2$ , the error is a few percent, and it is inconsequential for  $R/t \geq 5$ , where the overall approach applies.

The proper plastic strain can be found by subtracting the elastic strain, which depends on the current flow stress of the material:

$$\begin{aligned}\epsilon_p &= \epsilon_t - \frac{\sigma'_f}{E'} = \epsilon_t - \frac{1}{E'} \left( \sigma_0 + K \epsilon_p^n \right) \\ &= \epsilon_t - \frac{\sigma_0}{E'} + \frac{K \epsilon_p^n}{E'}\end{aligned}\quad (\text{Eq 56})$$

Equation 56 cannot be rewritten to find  $\epsilon_p$  explicitly, as required for substitution in the hardening law, but the result may be used nonetheless in evaluating the required integral numerically. Note that the third term on the right side of Eq 56 has been ignored throughout the previous derivations, thus enabling explicit evaluation of  $\epsilon_p$  from  $\epsilon_t$ . This has little effect for materials with typical hardening laws (Fig. 13).

For large  $R/t$  (small bending strain), the elastic core may make an appreciable contribution to the evaluation of the bending moment. (This was previously illustrated for the nonhardening case.) In this case, the integrals for  $\bar{T}$  and  $M$  are carried out over only the part of the thickness subjected to plastic strain. The results for hardening can be added to the elastic, perfectly plastic result (e.g., Eq 12) to obtain the full solution, as was illustrated in the previous section for pure bending.

The result for the plastic part of these quantities, say  $\bar{T}$  and  $\Delta M$ , is the same as Eq 52 and 53, with  $z_0$  replaced by  $z_1^*$  and  $z_2^*$ , where  $z_1^*$  and  $z_2^*$  are the location of the transitions from elastic to plastic behavior above and below the

neutral axis. That is:

$$\begin{aligned}\bar{T} &= -\frac{2z_0}{t} + \frac{K}{(n+1)\sigma_0} \left( \frac{t}{R} \right)^n \\ &\times \left[ \left( \frac{1}{2} - \frac{z_1^*}{t} \right)^{n+1} - \left( \frac{1}{2} + \frac{z_2^*}{t} \right)^{n+1} \right]\end{aligned}\quad (\text{Eq 57})$$

$$\begin{aligned}\frac{\Delta M}{w} &= K \left( \frac{1}{R} \right)^n \\ &\times \left[ \frac{(0.5t - z_1^*)^{n+2} + (0.5t + z_2^*)^{n+2}}{n+2} \right. \\ &\left. + \frac{z_1^*(0.5t - z_1^*)^{n+1} - z_2^*(0.5t + z_2^*)^{n+1}}{n+1} \right]\end{aligned}\quad (\text{Eq 58})$$

$$\begin{aligned}\frac{M}{w} &= \frac{2}{3} E' R^2 \left( \frac{\sigma'_0}{E'} \right)^3 + \frac{\sigma'_0}{4} \\ &\times [t^2 - 2(z_1^{*2} + z_2^{*2})]\end{aligned}\quad (\text{Eq 59})$$

Care must be taken using Eq 57 and 58 that  $z_0$ ,  $z_1^*$ , and  $z_2^*$  are not assigned nonphysical values outside of the sheet thickness. That is, the following rules apply to all of the calculations illustrated so far:

$$z_0 = \begin{cases} -\epsilon_m R & -\frac{t}{2} \leq -\epsilon_m R \leq \frac{t}{2} \\ \frac{t}{2} & -\epsilon_m R > \frac{t}{2} \\ -\frac{t}{2} & -\epsilon_m R < -\frac{t}{2} \end{cases}\quad (\text{Eq 60})$$

$$z_1^* = \begin{cases} z_0 + \frac{R\sigma'_0}{E'} & \frac{R\sigma'_0}{E'} \leq \frac{t}{2} \\ \frac{t}{2} & z_0 + \frac{R\sigma'_0}{E'} > \frac{t}{2} \end{cases}\quad (\text{Eq 61})$$

$$z_2^* = \begin{cases} z_0 - \frac{R\sigma'_0}{E'} & \frac{R\sigma'_0}{E'} \geq -\frac{t}{2} \\ -\frac{t}{2} & z_0 - \frac{R\sigma'_0}{E'} < -\frac{t}{2} \end{cases}\quad (\text{Eq 62})$$

Evaluation of Eq 58 and 59 (Table 3), shows that for  $0 < \bar{T} < 1$ , the maximum error caused by neglecting the elastic core is 0.17% ( $R/t = 25$ ) in sheet-forming range and grows to 4.6 and 13.8% for  $R/t$  of 100 and 200, respectively.

The foregoing results and discussions show that for the typical sheet-forming regions ( $5 < R/t < 25$ ), the elastic response of the material may be safely ignored, along with more complicated treatments of the strain and thick shells. For large  $R/t$ , the elastic strains become significant, and for smaller  $R/t$ , the thick-shell approach and proper plastic-strain measures become significant.

## Applied Analysis of Simple Forming Operations

For a typical industrial sheet-forming operation, the sheet workpiece is pressed between nearly rigid tools with draw-in constraints enforced, usually via draw beads. The general operation may be arbitrary in three dimensions, and conformance to the tools is by no means assured (Ref 58), thus making it impossible to know, a priori, the bend radius of the sheet. Many material elements undergo bending and unbending with superimposed tension, whereas the closed-form analyses usually assume a flat starting configuration in both in-plane directions. Determining sheet tension, which was shown in the last section to be critically important in springback, is complex, depending on friction, bending and unbending, and boundary constraints. All of these variables may change throughout the part and the forming stroke, over small distances and times.

For arbitrary, three-dimensional (3-D) forming operations, FE analysis (or a similar numerical method) is required throughout the forming operation to obtain a final, as-formed state. This configuration (with tool contact forces) may then be used as a basis for a general springback

**Fig. 11** Role of normalized sheet tension and bend radius on springback for elastoplastic, hardening behavior (Eq 58 and 59) of low-strength steel (Eq 26). See Eq 7, 58, and 59.  $r$ , radius of curvature after springback;  $R$ , radius of primary bending curvature;  $t$ , sheet thickness

**Fig. 12** Comparison of bending moment using thin and thick shells, with either engineering strain or true strain.  $\bar{T}$ , normalized sheet tension

analysis using the same, or a different, FE model. Such analysis is discussed subsequently; however, the application of two-dimensional (2-D) closed-form methods is possible and profitable for some classes of forming operations that are first mentioned.

In spite of the difficulties of applied springback analysis discussed previously, certain applied problems have sufficiently restrictive characteristics to provide a basis for closed-form or empirical analysis. Pure bending by dies in two dimensions, for example, may be analyzed using closed-form bending solutions if the workpiece is assumed to conform to the punch surface. Results have been presented for U-bending and V-bending (Fig. 14) using such analysis (Ref 32, 59–63) and empirical approaches (Ref 36, 64–66). A closely related application in sheet metal forming is flanging, for which analysis (Ref 67) and empirical approaches (Ref 68) have been presented.

Closely related operations involving significant tension are often called stretch-bend or draw-bend problems. These operations involve the bending and unbending of sheet as it is progressively drawn over a die. The typical application is often referred to as a top-hat section (Fig. 1c, 15a) and may be called channel forming, among other common names. For large draw-in, the principal springback typically occurs in the form of sidewall curl, which is the curling of the material that was drawn over the die radius (and which was flat while the workpiece was held in the dies during the operation itself). Various analyses based on the methods presented in the last section have appeared (Ref 23, 47–54, 57, 69, 70) and empirical methods have been applied (Ref 71, 72). Such analysis has been extended to consider the differing roles of postbending tension versus prebending tension (Ref 47), laminated materials (Ref 56), and nonuniform bending (Ref 55).

Much of the experimental work appearing in the literature for draw bending must be examined

critically because the tensile stress or load is often not carefully controlled or measured. In a few exceptional cases (Ref 53, 73, 74), direct control was imposed to obtain draw-bend results. For other work, experiments rely on indirect control of tension via friction, draw beads, or die clearances to establish the essentially unknown value of sheet tension. As shown in the last section, the tensile stress has a dominant effect on springback, particularly for values approaching the yield tension, thus leading to large uncertainties in measured results unless the tensile stress is known accurately.

A wide range of experimental data for a draw-bend problem from various sources appears as part of the NUMISHEET '93 *U-Channel Benchmark* (Ref 75). Geometry, material, lubrication, and forming parameters were fully specified by the conference organizers, and numerous laboratories were asked to carry out independent measurements and simulations. The results, shown in Fig. 15(b), illustrate the wide scatter that was obtained. In general, the experimental scatter was greater than or equal to the simulation scatter, illustrating the difficulty in carrying out such experiments with normal industrial forming machinery. It appears that the scatter of experimental results is typical for experiments employing indirect control of sheet tension. The sources of error for the FE simulations are considered in more detail

**Table 3** Maximum error in moment caused by neglecting elastic core for  $0 < \bar{T} < 1$ , low-strength steel (Eq 26)

$R/t$	Maximum error in moment, %

subsequently, along with a summary of draw-bend results for which the sheet tension is carefully controlled.

### Finite Element Analysis

It is only through a complete analysis of the forming operation that the critical variables in springback analysis may be obtained reliably, notably sheet tension, prespringback part shape, distribution of internal properties (such as yield strength), and external loading/internal stresses prior to springback. The geometric complexity of general bodies with curves in three dimensions (such as typical autobody parts, for example) requires discretized treatment. However, finite

**Fig. 14** Schematics of V-bend and U-bend forming operations

**Fig. 15** U-channel forming and benchmark results. (a) Cross-sectional geometry, after springback. (b) Simulation results (points) and superimposed estimated experimental scatter (bars) for results reported by various laboratories.  $\theta_1$  and  $\theta_2$ , angles characterizing springback in top-hat samples;  $\rho$ , radius of curvature of sidewall curl

element analysis (FEA) offers several other advantages as well. Most FE programs readily accept complex laws of material behavior, including anisotropy, elastic-plastic behavior, rate sensitivity, complex hardening, and so on. The more sophisticated programs handle large strain and rotation properly, and arbitrary geometry is treated naturally.

The FEA of sheet forming is well established and now routine (see, for example, various benchmark tests on the subject) (Ref 1, 75–78). The FEA of springback, while appearing to be a simpler problem, requires higher accuracy of both the forming solution and throughout the springback simulation (Ref 39, 41, 79, 80). The choice of element (Ref 38), unloading procedure (Ref 39, 55, 81), and integration scheme (Ref 38, 39, 62, 80, 82, 83) must all faithfully reproduce the stresses and part configuration.

In view of the need for high precision of stress results, implicit forming simulation and implicit springback schemes seem the most likely to succeed (Ref 82). However, claims of success have appeared for nearly every possible combination of procedure: implicit/implicit (Ref 38, 39, 41, 84, 85), explicit/implicit (Ref 79, 82, 83, 86, 87), explicit/explicit (Ref 88, 89), and one-step approaches (Ref 90).

In the section “Draw-Bend Experience” in this article, these general observations are probed with tests and simulations corresponding to draw-in over a die radius in a press-forming operation. In order to understand those results, a brief introduction to the FE method is first presented.

A presentation of the FE method is beyond the ambit of this article. Nonetheless, an understanding of the basic method is helpful in understanding the particular constraints presented by springback analysis following forming analysis.

The following is based on a presentation of FEA particularly aimed at metal forming (Ref 91). Numerous books on the subject of general-purpose FEA have appeared. References 92 to 97 may be of interest for those seeking additional information. They are presented in approximate order of increasing difficulty.

The FE method applied to forming analysis consists of the following steps:

1. Establish the governing equations: equilibrium (or momentum for dynamic cases), elasticity and plasticity rules, and so on.
2. Discretize the spatially continuous structure by choosing a mesh and element type.
3. Convert the partial differential equations representing the continuum motion into sequential sets of linear equations representing nodal displacements.
4. Solve the sets of linear equations sequentially, step forward and repeat.

Items 1 and 2 of this list are of particular importance for springback analysis. For item 1, many choices of material model may be used,

but most forming simulations rely on two basic governing equations: either static equilibrium is imposed in a discrete sense (i.e., at nodes rather than continuous material points), or else a momentum equation in the form of  $F = MA$  is satisfied for dynamic approaches.\* For nearly all commercial codes used for metal forming, the static equilibrium solutions are obtained with implicit methods that solve for equilibrium at each time step by iteration, starting from a trial solution. Thus, such programs are often referred to as static implicit. Examples of static implicit include ABAQUS Standard (Ref 98) and ANSYS (Ref 99). Forming programs that solve a momentum equation typically use explicit methods that convert unbalanced forces at each time increment into accelerations but do not iterate to find an assured solution. Examples include ABAQUS Explicit (Ref 100) and LS-DYNA (Ref 101).

The choice of element refers to the number of nodes per element, the number of degrees of freedom at each node, and the relationship with the assumed interior configuration (among other things) that define the element type. The nodal displacements are the primary variables to be solved for. A fixed relationship between the displacements of points within the finite element to the displacements of the nodes is assumed. In this way, the continuous nature of the deformation within the element is related to a small number of variables. Of course, the distribution in the element may be quite different from the continuum solution, but this difference can often be progressively reduced by refining the mesh, that is, by choosing finer and finer elements. By comparing the solutions, an adequate mesh size can be determined.

The essence of the FE method, as opposed to other discrete treatments such as the finite difference method, lies in an equivalent work principle. As described previously, the continuous displacements within an element are represented by a small number of nodal displacements (and possibly other variables) for that element. Similarly, the work done by the deformation throughout the element is equated to the work done by the displacements of the nodes and thus are defined equivalent internal forces at these nodes.\*\* The internal work is computed by integrating the stress-strain relation over the volume of the element. This frequently cannot be accomplished in closed form, so certain sampling points, or integration points, inside the element are chosen to simplify this integration. The number and location of integration points may be selected to provide the desired balance between efficiency and accuracy, or between locking and hourglassing, as mentioned subsequently.

For forming and springback analysis, the procedure consists of applying boundary conditions (i.e., the motion of a punch or die, the action of draw beads, frictional constraints, and so on), stopping at the end of the forming operation, replacing the various contact forces

by fixed external forces (without changing the shape of the workpiece), and then relaxing the external forces until they disappear. The last step (or steps) produces the springback shape.

Because the choices of program, element, and procedure usually apply to both the forming and springback steps, it is difficult to separate discussions of accuracy between the two stages. The deformation history established in the forming operation is used in the springback simulation via the final shape, loads, internal stresses, and material properties.

Two choices are of particular importance in forming and springback analysis: the type of solution algorithm/governing equation, and the type of element. These two aspects are discussed as follows.

**Explicit and Implicit Programs.** The first choice facing one wishing to do forming/springback analysis is the type of program. As noted previously, the two standard choices are a dynamic explicit program or a static implicit program, although several companies have both options available, sometimes even during a single simulation. (Also, there are other variations available, such as dynamic solutions solved implicitly.) Table 4 lists general advantages and disadvantages of the two methods.

Most applied sheet-forming analysis in industry currently uses dynamic explicit methods. The complicated die shapes and contact conditions that occur in complex industrial forming are more easily handled by the very small steps required by the dynamic explicit methods. The stress solutions are of little importance. Often, even simulations that are inaccurate in an absolute sense can be used by experienced die designers to guide sequential modifications leading to improved dies. On the other hand, if a certain set of tools cannot be simulated successfully, that is, with an implicit method that does not converge, the die improvement process is stymied completely.

As is shown in the next sections, springback simulation is much more sensitive to numerical procedure than forming analysis. The reason is simple: springback simulation relies on accurate knowledge of stresses throughout the part at the end of the forming operation. Conversely, forming analysis is primarily concerned with

\*It should be noted that nearly all commercial forming operations may properly be considered static. That is, the inertial forces are orders of magnitude smaller than the deformation forces and thus may be safely ignored. The use of dynamic solutions to solve such quasi-static problems is for numerical convenience, with a corresponding loss of accuracy whenever the inertial forces are magnified (by mass scaling, for example). Thus, mass scaling must always be examined to quantify the errors introduced.

\*\*Equilibrium in a weak sense is imposed by requiring that the sum of all such internal forces is zero at each node. Compatibility in a weak sense is automatically satisfied because the common nodes of adjacent elements have a single displacement. These are called weak forms because they do not ensure equilibrium or compatibility throughout the entire body, only at the nodes.

the distribution of strain within the shape of the part. The shape of the final part is largely determined by the shape of the dies because, near the end of the forming operation, contact occurs over a large fraction of the workpiece. Therefore, the oscillatory nature of the stresses obtained at the end of a dynamic explicit analysis may be unsuited for accurate springback analysis. Poor and uncertain results have been reported (Ref 82).

Developments are currently proceeding in attempts to artificially smooth or damp dynamic explicit forming solutions in the hope of providing a stable base for springback calculations. It is too early to be confident that these approaches will be successful. Certain isolated results can appear promising; however, as is shown later in this section, it is not unusual to obtain fortuitously accurate results in springback analysis. For this reason, great caution should be used in drawing conclusions from a small number of apparently accurate predictions.

The foregoing refers to the drawbacks of a dynamic explicit simulation of a forming operation prior to a springback analysis. The springback simulation itself is also much better suited to implicit methods because the operation is dominated by quasi-static elastic deformation that is computed very inefficiently by dynamic explicit methods. For this reason, implicit springback analysis is often favored even after explicit forming analysis.

It is for these two reasons that static implicit methods are better suited to forming analysis where accurate springback predictions are required. The obvious drawback is the uncertain convergence of current versions of such methods.

**Choice of Element.** For sheet-forming analysis, two principal kinds of elements are popular, although nearly limitless variations are found within each category. The major choices are solid elements and thin-shell elements.

The simplest to understand is the standard eight-node, trilinear solid element, sometimes called a brick element. (When an element is described as linear or quadratic, it refers to the polynomial order of the shape function, that is,

the mapping equation that relates the motion of the nodes to the motion of the continuous interior points in the element. In a linear element, the displacements of interior points vary linearly with their original positions. Trilinear refers to a shape function that is linear in all three dimensions.) The incompressibility constraint of plastic deformation is readily adapted with this element, and it is used for a variety of structural applications, including bulk forming. The major disadvantage is simple: because many such elements are required through the thickness of the sheet, particularly to accommodate springback analysis, the final number of degrees of freedom for applied problems is enormous and the resulting computation time far beyond today's (2005) computers. Such elements are also typically very stiff in bending, thus making them very poor for springback. One improvement is the use of quadratic or higher-order elements, which have better bending behavior, but which add even more degrees of freedom and further aggravate the overwhelming computational intensity.

Many variations of the standard brick element have been introduced with the goal of enabling use of coarse meshes without locking (nonphysically high stiffness in certain modes of deformation). Unfortunately, these numerical corrections often introduce the converse phenomenon of hourglassing (nonphysically low stiffness in certain modes of deformation). New solid elements can balance these problems well, but often at the cost of complexity (Ref 102, 103). Unfortunately, even with elements optimized for coarse meshes, the numbers still overwhelm today's (2005) computers for applied sheet-forming analysis, because very small features must be simulated.

By far, the predominant element used for sheet-forming analysis is the thin-shell element, or simple shell element. One can imagine generating such an element by starting with solid elements and shrinking one dimension to small thickness, a strategy that has been pursued (Ref 104, 105). Unfortunately, this procedure leads to locking, and special integration methods (reduced integration, selective reduced

integration, assumed strain methods, and so on) are then necessary to recover reasonable behavior.

Typical shell elements for sheet forming are based on some version of thin-shell theory, which itself makes assumptions about the strain and stress state throughout the body. They may be triangles or quadrilaterals, although quadrilaterals are more common. There is no real thickness to the elements, so clearances between die faces can be a problem in FE simulations where that aspect is important. Usually, the strain is assumed to vary linearly through the "thickness" of the shell for purposes of evaluating the stresses and work of deformation.\* Likewise, through-thickness stresses are usually ignored. The usual procedure introduces two new degrees of freedom at each node corresponding to the slope or local rotation of the material plane at that location.

The advantages of shells for applied sheet forming and springback analysis are so persuasive in today's (2005) computing environment that solids are seldom used except for research or when certain conditions are present. These conditions include critical die clearances, two-sided contact, significant through-thickness stresses, and  $R/t$  ratios less than 5 to 6. Outside of these cases, shell elements are many times more efficient, and they capture the necessary phenomena in most sheet-forming operations, which are dominated by bending and stretching.

### Draw-Bend Experience

The advantages and pitfalls of FEA of springback for many sheet-forming operations are revealed by the draw-bend test (Fig. 16), which closely represents the situation in channel forming (Fig. 14b, 15a) and many other press-forming operations. The advantage of the test is that sheet tension may be closely controlled.

The material in the test is drawn over a round tool under the action of a pulling displacement (and corresponding front force) and resisting force (back force). The workpiece may or may not conform completely to the tool surface when under load; it undergoes bending and then unbending under tension, then rebending under the final unloading when it is released from the fixtures. When released, the drawn length of the strip specimen adopts a final radius of curvature ( $r'$ ). This is precisely analogous to the channel-forming operation, where the pulling displacement is provided by the punch displacement, the back force is provided by a draw bead or frictional resistance over a binder

**Table 4 Advantages and disadvantages of static implicit and dynamic explicit finite element programs**

Program type	Advantages	Disadvantages
Static implicit	<ul style="list-style-type: none"> <li>Known accuracy</li> <li>Equilibrium satisfied</li> <li>Smooth stress variation</li> <li>Elastic solutions are possible</li> <li>Unconditionally stable</li> </ul>	<ul style="list-style-type: none"> <li>Solution not always assured</li> <li>Complex contact difficult to enforce</li> <li>Long computer processing times for complex contact</li> </ul>
Dynamic explicit	<ul style="list-style-type: none"> <li>Solution always obtained</li> <li>Simple contact</li> <li>Short computer processing times with mass scaling</li> </ul>	<ul style="list-style-type: none"> <li>Uncertain accuracy</li> <li>Equilibrium not satisfied in general</li> <li>Mass scaling introduces error in static problems</li> <li>Oscillatory stress variation</li> <li>Elastic solutions are difficult and slow</li> <li>Conditionally stable</li> </ul>

\*In the limit of no thickness, and consequently no bending stiffness, a thin-shell element becomes a membrane element. These elements are efficient because they do not require additional degrees of freedom at the nodes, but they are unstable in bending, a common mode for many sheet-forming operations.

surface, and the final radius of curvature of the drawn section is referred to as sidewall curl. When the drawn distance is sufficiently large, the final springback changes are dominated by the sidewall curl (radius  $r'$ ) rather than the changes in the small region in contact with the tool at the end of the test.

Results of draw-bend tests and parallel FE simulations (Ref 40, 74) form the basis for the following observations.

**Numerical Parameters.** Finite element sensitivity studies (Ref 38, 39, 106) of the draw-bend test revealed that accurate springback prediction requires much tighter tolerances and closer attention to numerical parameters than does forming analysis. Furthermore, the tighter tolerances must be maintained throughout the forming operation; that is, it is not sufficient to do a coarse forming simulation followed by a precise springback simulation (Ref 82).

Using meshes, tolerances, and numerical parameters typical for forming analysis to analyze the draw-bend test gave nonphysical predictions, including, under some conditions, simulated springback opposite to the direction observed. Figure 17(a) (Ref 38) shows the initial simulations and the final ones (i.e., with appropriate choices of model parameters). A mesh size four times finer along the draw direction was required, combined with a number of integration points ten times larger than normal.

The FE sensitivity results based on the draw-bend test may be summarized as:

- The finite elements in contact with tooling should be limited in size to approximately 5 to 10° of turning angle. This is approximately 2 to 4 times the refinement typically recommended for simulation of forming operations.

**Fig. 16** Schematics of the draw-bend test and final configuration of the unloaded specimen.  $F_b$ , normalized back force;  $R$ , tool radius;  $R'$ , radius of curvature of region in contact with tool, after unloading;  $r'$ , radius of curvature in curl region, after springback;  $\Delta\theta$ , springback angle;  $\Delta X$ , displacement, the distance between the original and final positions;  $\dot{X}$ , displacement rate

- The convergence tolerance and contact tolerance must typically be set tighter than for forming analysis. There are a variety of ways to define such measures, depending on the programs used, so again, the best policy is to refine the measure until the differences become insignificant.
- While most applied sheet-forming analyses use shell elements with three to seven integration points through the thickness, up to 51 integration points are required to assure simulated springback results within 1% of the “converged” solutions. (Converged solutions were obtained by using very large numbers of integration points, until no appreciable change in springback was observed.) More typically, 25 integration points were found to be sufficient for many simulations.

The last of these conclusions represents a dramatic divergence from current practice and remains surprisingly controversial, with researchers continuing to recommend using numbers of integration points ranging from five to nine (Ref 107–111). For this reason, non-FEA numerical studies (Ref 112, 113) were undertaken to explore the errors associated with numerical integration for finite numbers of integration points. Results from the FE sensitivity studies are presented first, then those from the non-FEA numerical studies. The two approaches serve to confirm the main conclusions.

Figure 17(b) (Ref 39) shows a typical result of the FE sensitivity analysis for tests of 6022-T4 aluminum with  $R/t$  of 10. In one case, for a normalized back force of 0.9 (relative to the force to yield the strip in tension), 35 integration points were required to meet the 1% tolerance requirement, while for a back force of 0.5, only 21 integration points were required. It is important to note the following points with respect to these results:

- The choice of  $R/t$ , back force, and other process and material parameters changes the number of required integration points. However, there is currently no good way to predict the exact number before a simulation is carried out, because many of these quantities are available only after solving the boundary-value problem. As shown subsequently, the effect of process variables on the required number of through-thickness integration points can be determined. Therefore, 25 to 51 integration points are recommended for general cases (if 1% accuracy of springback prediction is desired). As with all FEA, the best policy is to refine the parameters (number of integration points, in this case) to verify that no significant changes take place with continued refinement.
- It is possible, by chance, to obtain accurate results for a given forming problem with a small number of integration points. Note that the results in Fig. 17(b) cross the converged solution several times, with as few as three to five integration points. However, the result

is fortuitous and cannot be assured unless many more integration points are employed. Extrapolating from this result may explain why seemingly rough simulation techniques (such as dynamic explicit solutions, which show oscillatory stress behavior) can produce, with carefully selected (postsimulation) parameters (or sufficient luck!), accurate springback results. The best way to verify the robustness and predictivity of such solutions is by changes of the critical parameters to test whether the solution is a stable one.

- Many 3-D forming operations are much stiffer than the 2-D draw-bend geometry because of the final form of the part. It is unknown what effect this has on the need for numerical accuracy. However, it is clear that for smaller springback, a larger percentage error may be acceptable in terms of the overall geometry changes. Thus, it may not be necessary to demand a 1% springback accuracy; instead, perhaps 10% is adequate. In such cases, the number of integration points may be reduced.

The FEA sensitivity results for the draw-bend test can be understood with the aid of a related but simpler problem: the springback of a beam subjected to an applied  $R/t$  and tension force. That is, the state after forming is known analytically, and only the springback is computed, both analytically and numerically. The springback is proportional to the applied moment (Eq 4) so that any fractional numerical error that occurs in evaluating the moment produces a corresponding fractional error in the computed springback. The analytical moment (and springback) may be computed exactly for this problem, and thus, the error induced by the numerical integration scheme during the springback simulation alone can be evaluated separately from other effects. This error is less than the combined errors that can occur during both the forming and springback stages of a simulation.

The following results are extracted from more detailed publications that should be consulted by those seeking more complete information (Ref 107, 108). Equations 57 to 62 represent the analytical tension and moment calculations. Material models were adopted representing a low-strength steel and high-strength aluminum (Eqs 26, 27). Numerical integrations were carried out with three common choices of integration rules: trapezoidal (Ref 114), Simpson (Ref 115), or Gauss (Ref 116). Figure 18 presents the fractional moment error for the low-strength steel bent to  $R/t = 5$  using a trapezoidal integration rule with 51 integration points through the thickness ( $N_{IP}$ ) for various normalized sheet tension forces. (The normalized sheet tension force is defined by dividing the applied tension force by the force to yield the sheet, which is equal to the yield stress times width times thickness of the sheet.) The range of sheet tensions considered is from zero (pure bending case) to  $\bar{T}_{max}$ , where  $\bar{T}_{max}$  is the normalized sheet

tension force where the entire thickness of the sheet is plastically deforming; that is, the elastic core has moved to the edge of the sheet. For the low-strength steel at  $R/t = 5$ ,  $\bar{T}_{\max}$  is 2.06.

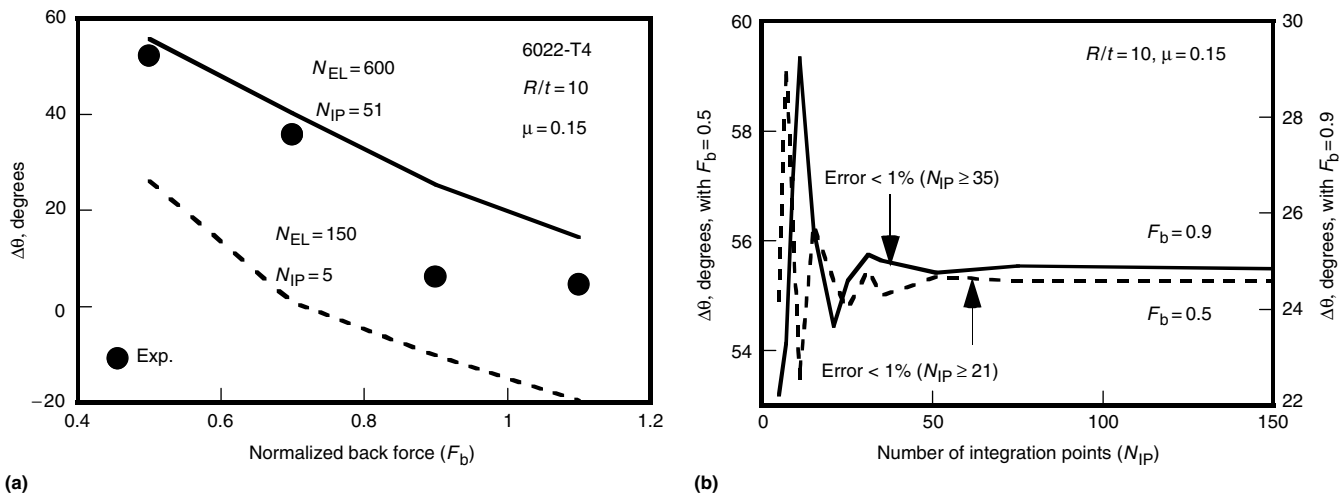

Two conclusions can be drawn from the set of computations shown in Fig. 18. First, the errors fall into a range depending on the exact choice of parameters. For some particular cases, the error may be zero, while at nearby adjacent states the error may be maximum. (For Fig. 18, this effect can be observed by small changes of the normalized tension force.) The behavior is oscillatory (as most easily seen in Fig. 18 at smaller tension forces), depending on where the integration points fall relative to the actual through-thickness stress distribution. The smooth lines drawn on Fig. 18 represent the assured error limit, that is, the limit of error in the vicinity of a

given set of conditions. For any set of conditions and numerical integration choices, the numerical integration error will always be less than or equal to this assured error limit, but the actual error in the nearby vicinity of those conditions may be anywhere from zero to this value. In this manner, the bounding error limit can be defined.

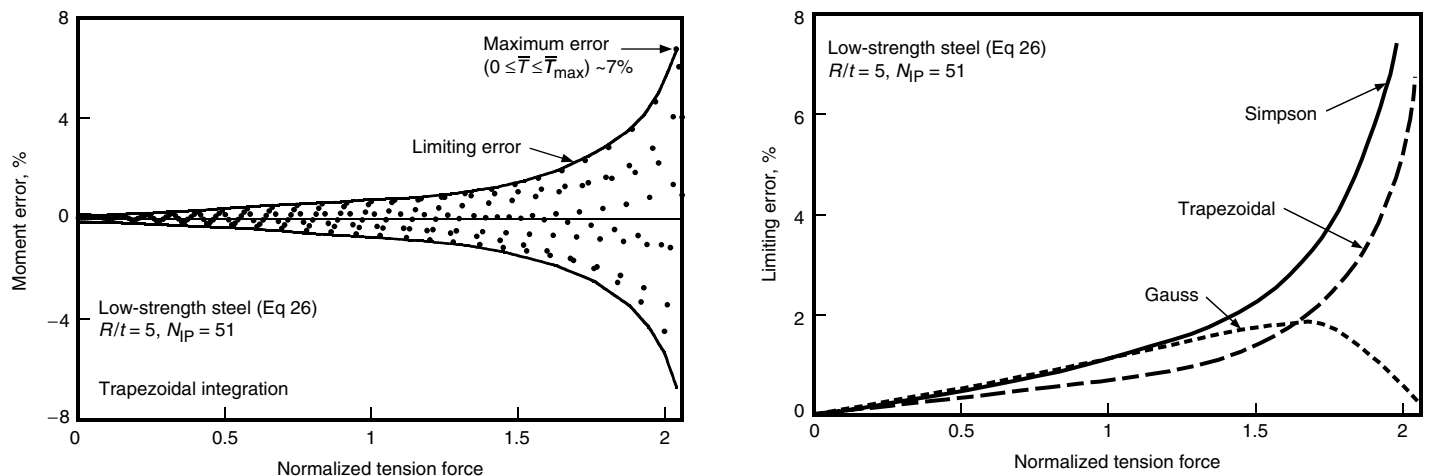

The second conclusion illustrated by Fig. 18 is that the assured fractional moment error (or, more succinctly, limiting error) increases for increasing sheet tension. This can be understood in terms of the decreasing moment with increasing sheet tension. Thus, a given absolute error in reproducing the analytical stress distribution by numerical integration technique represents a larger fractional error of moment (or springback). While assured fractional moment error is increased for larger sheet tensions, note that the

oscillatory behavior still exists, so it is possible in the vicinity of any sheet tension to obtain a particular result with nearly zero error. Such an isolated result is fortuitous and should not be relied on to estimate future performance.

A comparison of the three tested integration methods (Fig. 19) shows that no single integration method works best throughout the range of parameters. In view of the oscillatory nature of the error, for any given set of conditions, any one of these may outperform the other two. In Fig. 19, the unsigned assured error limit is presented. This error limit is smaller at low back forces for trapezoidal integration, while Gauss integration is better at higher normalized tension forces. This may be simply understood by noting that the stress distribution is smoothest in this region, most like a polynomial, and thus

**Fig. 17** Sensitivity of simulated draw-bend springback to mesh size ( $N_{EL}$ ) and number of through-thickness integration points ( $N_{IP}$ ). (a) Nonphysical springback predictions obtained using typical sheet-forming simulation parameters. (b) Accuracy of selected springback solutions depending on the number of through-thickness integration points.  $\Delta\theta$ , springback angle;  $R/t$ , ratio of bending radius to thickness;  $\mu$ , friction coefficient

**Fig. 18** Fractional error of computed moment (or springback) using trapezoidal integration and 51 integration points ( $N_{IP}$ ) through the thickness. The limiting error (i.e., the assured maximum error in the vicinity of a set of conditions) is shown as smooth curves, and the maximum error occurs for a normalized tension force of 2.06 ( $\bar{T}_{\max}$ ).  $R/t$ , ratio of bending radius to thickness

**Fig. 19** Comparison of the variation of limiting error (unsigned) with normalized tension for three common integration schemes using 51 integration points ( $N_{IP}$ ) through the thickness.  $R/t$ , ratio of bending radius to thickness

is reproduced better by Gauss integration in general. Because the largest possible fractional errors occur at larger tension forces, the Gauss integration scheme is a good choice (but by no means the best for all cases).

The role of  $R/t$  in affecting integration error is illustrated in Fig. 20. A maximum error is defined, as shown in Fig. 18 and as plotted in Fig. 20. That is, this quantity represents the assured fractional error limit for a range of normalized tension forces between 0 (pure bending) and  $\bar{T}_{\max}$  (where the entire thickness yields plastically in tension). This maximum error is of interest because for most forming operations, the value of the tension force is unknown except after the forming simulation is completed. Furthermore, it varies with time and location in the workpiece, as does  $R/t$ . Therefore, the maximum error must be considered as the numerical tolerance when performing a forming/springback simulation without *a priori* knowledge of the sheet tension. The maximum error is highest for small  $R/t$  values and lowest for larger  $R/t$ . Note the different scales on Fig. 20(a) and (b), illustrating the larger fractional errors for the low-strength steel.

A summary of many results such as those in Fig. 18 to 20 is presented in Fig. 21 and Table 5. Both may be used to determine the number of integration points needed to assure a limiting fractional error based only on numerical integration errors. (Of course, other sources of error, for example, incurred during the forming simulation or by other numerical aspects, can contribute to larger overall errors.) Note that Gauss integration is usually more efficient because, in the regime where the fractional springback errors are largest, it reproduces the analytical result best. The required number of integration points for a specified accuracy varies widely. For an assured 1% error tolerance, Gauss integration requires between 17 and 68 integration points through the thickness (depending on  $R/t$  and

material properties), while Simpson integration requires between 35 and 139 integration points through the thickness. For 10% tolerance, Gauss integration requires 5 to 16, depending on  $R/t$  and material properties, while Simpson requires 9 to 41.

**Choice of Element,  $R/t$ , Anticlastic Curvature.** Shell elements are preferred for springback simulation of sheet metal forming, because they can capture the bending behavior accurately while being computationally efficient as compared with solid elements, as long as the material thickness is small relative to the radius of bending. Membrane elements exclude bending effects and thus miss the major part of springback, while solid elements are very time-consuming for use with sheets because numerous layers must be used through the thickness (for the same reasons that many integration points are required for shells).

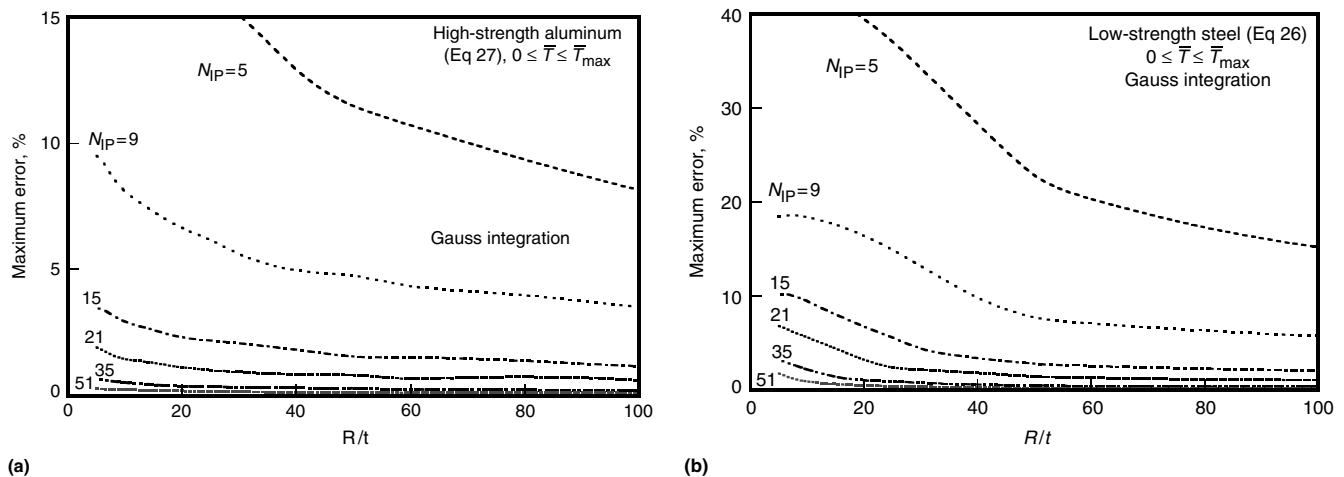

Draw-bend tests and simulations for drawing-quality special killed steel (Fig. 22a) showed that shell elements are accurate for  $R/t$  ratios as small as approximately 5 or 6, while solid elements are needed for smaller values, at much increased cost. Solid elements capture the through-thickness stresses that become significant for small  $R/t$ , but the typical brick elements with linear shape functions are very stiff in bending and provide poor results (Fig. 22b). For this reason, higher-order solid elements are preferred. For larger  $R/t$  ratios, shell elements normally provide better accuracy at much lower computation time.

One surprising result from the draw-bend simulations is that 3-D elements are required for the nominally 2-D problem (Fig. 22b). The answer lies in anticlastic curvature, discussed more fully in the section “Approximations in Classical Bending Theory” in this article. This is the secondary curvature that develops orthogonal to bending because of differential lateral contraction at the inner and outer

surfaces. As shown in Fig. 23, 3-D shell elements and 20-node quadratic solid elements capture the anticlastic curvature well, whereas 2-D elements and linear solid elements do not. Poor treatment of anticlastic curvature is the principal source of error in springback prediction for the draw-bend tests with back forces near the yield force. For arbitrary 3-D parts, the analog of anticlastic curvature causes distortion or wrinkling out of the plane of bending, as can be seen in the dimpling of the S-rail (Fig. 1a).

**Unloading Scheme.** Another surprising result from the draw-bend simulations is the importance, under some conditions, of plastic deformation during unloading. A comparison of 2-D simulation results is shown in Fig. 24, where the unloading was carried out purely elastically and elastic-plastically. Significant differences of the springback angle and residual stress are evident. However, it should be noted that in spite of the small plastic contribution to unloading behavior under some circumstances, the choice of path taken during unloading seems to have no significant effect on the final configuration (Ref 39). That is, the various unloading schemes and sequences for removing the tool constraints seem to give nearly identical results. It should also be noted that for many springback problems, particularly those with fairly small tension forces relative to yielding, the unloading will be purely elastic.

**Plastic Constitutive Equation.** At least two aspects of the plasticity law are important for springback prediction: plastic anisotropy (yield stress and strain ratios) and strain hardening. In particular, strain hardening must be suitable for a path reversal in draw-bend or channel-type forming, as is encountered when a material element undergoes sequential bending and unbending with superimposed tension (Ref 117). The yield surface anisotropy affects not only

**Fig. 20** The maximum error (that is, for sheet tensions from 0 to  $\bar{T}_{\max}$ ) as a function of the ratio of bending radius to thickness ( $R/t$ ) for various numbers of integration points ( $N_{IP}$ ). (a) For material properties corresponding to a typical high-strength aluminum (Eq 27,  $E = 70$  GPa, where  $E$  is Young's modulus). the loaded bending moment but also the anticlastic curvature via the lateral strain ratios (related to the plastic anisotropy parameter,  $r$ , in various directions).

Table 6 compares the standard errors of fit for the simulated draw-bend springback angles for 6022-T4 aluminum alloy with  $R/t = 10$  and normalized back forces ranging from 0.5 to 1.05.

**Fig. 21** Summary of the relationship between the maximum fractional error (for normalized sheet tension between 0 and  $\bar{T}_{\max}$ ) in moment (or springback) as a function of the number of integration points ( $N_{IP}$ ) used with Gauss quadrature for several typical process and material parameters.  $R/t$ , ratio of bending radius to sheet thickness

**Table 5** Number of through-thickness integration points ( $N_{IP}$ ) required for a specified springback accuracy. Numbers without parentheses refer to Gauss integration; numbers in parentheses refer to Simpson integration

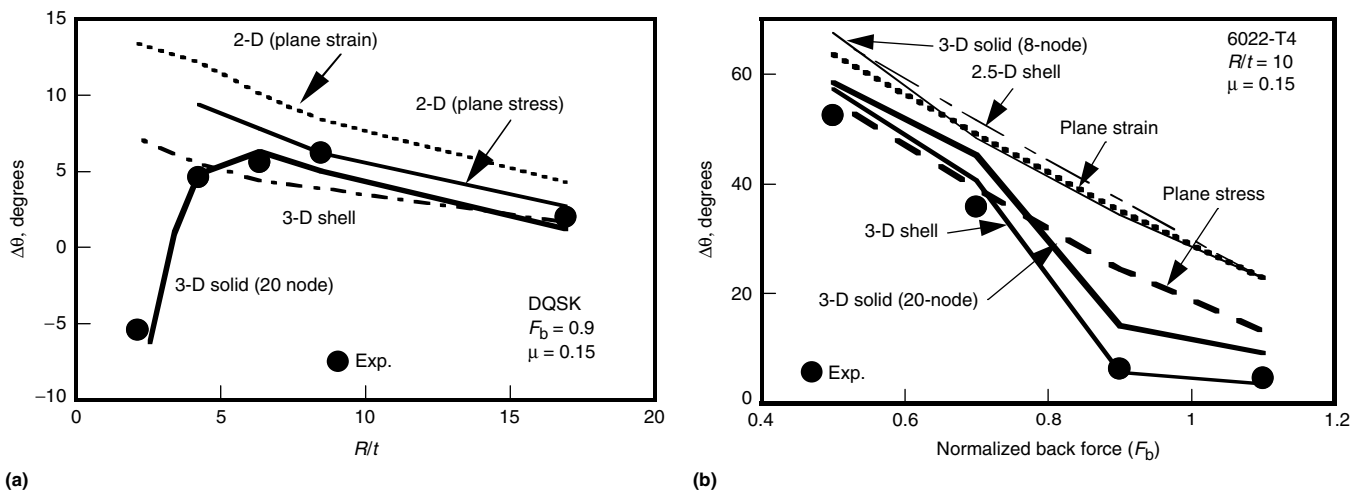

Maximum error	1%	5%	10%	50%
<b>Low-strength steel (<math>0 \leq \bar{T} \leq \bar{T}_{\max}</math>)</b>				
$R/t = 5$	68 (139)	26 (69)	16 (41)	4 (9)
$R/t = 20$	38 (91)	18 (37)	13 (29)	4 (9)
$R/t = 100$	22 (57)	10 (23)	6 (15)	3 (7)
<b>High-strength aluminum (<math>0 \leq \bar{T} \leq \bar{T}_{\max}</math>)</b>				
$R/t = 5$	30 (79)	13 (33)	9 (21)	4 (7)
$R/t = 20$	22 (55)	11 (25)	7 (15)	4 (7)
$R/t = 100$	17 (35)	8 (15)	5 (9)	3 (5)

$\bar{T}$ , normalized sheet tension;  $R/t$ , ratio of bending radius to sheet thickness

The results illustrate that choosing an anisotropic yield function gives no guarantee of improved results. The Hill 48 quadratic yield function (Ref 23) gives significantly poorer fit than the von Mises isotropic yield function. The reason for this result is shown in Fig. 25, where the variation of yield stress and strain ratio with direction is poorly matched by the Hill 48 yield function and well represented by the Barlat YLD 96 (Ref 118) yield function. These results are presented and discussed in more detail in the literature (Ref 119), including excellent final prediction of anticlastic curvature. There are likely compensating effects of the yield stress variance and strain-ratio variance for the von Mises simulations that are not easily deconvoluted in predicting the final springback angle.

For all choices of yield function, taking into account the Bauschinger effect improves the prediction, as would be expected based on the reverse straining that takes place for most material elements throughout the draw-bend process (Ref 119).

**Summary.** The relative errors induced by the various factors discussed previously are illustrated in Fig. 26. Using normal forming simulation parameters (mesh size, integration points) and standard plastic laws (von Mises, isotropic hardening) for 2-D springback simulation leads to very poor results, including springback of the wrong sign (Fig. 17a, for example). The overall standard error of fit to the measured values is 26°. The 2-D simulations using adequately selected numerical parameters reduce the error to 19° (plane strain) and 11° (plane stress). Use of 3-D shell elements for simulation (i.e., taking anticlastic curvature into account) reduces the error to 5.7°. Incorporation of the proper yield function form, Barlat YLD 96 (Ref 118), and a treatment of the Bauschinger effect (Geng-Wagoner hardening, Ref 119) reduce the final error to 1.2°, approximately the same magnitude as the experimental scatter of the measurements.

**Fig. 22** The role of finite element type on draw-bend springback prediction. (a) Results for various  $R/t$  (bend radius/sheet thickness). (b) Results for various  $F_b$  (normalized back force).  $\Delta\theta$ , springback angle; DQSK, drawing quality special killed;  $\mu$ , friction coefficient

Therefore, while it is essential to perform springback simulations carefully and to properly take into account the material behavior, it is possible to predict springback accurately for general cases. The biggest challenge for large-scale industrial applications lies with the convergence of implicit solutions during forming and the computational intensity of such simulations.

### Springback Control and Compensation

The prediction of springback has been discussed in some detail at various levels of complexity in the foregoing sections. However, practical mitigation of springback in industry relies on two principal strategies: control (reduction) of springback via forming operation changes, and compensation for springback via changes of die shape. These two approaches

are discussed briefly, with references to original works provided.

**Control of Springback.** As illustrated in Fig. 10, application of sheet tension, particularly near the tension to yield of the sheet, drastically reduces springback by reducing the stress gradient through the thickness and hence the bending moment. Most industrial schemes for reducing springback rely on this principle. However, increasing sheet tension moves a forming operation closer to failure by splitting (Ref 47), such that many optimized forming operations walk a fine line between splitting and excessive springback.

Most springback control methods focus on increasing the sheet tension while mitigating the negative effect on formability. The tension can be applied during the drawing part of the forming operation or subsequently (Ref 48, 71). By the use of a variable blank-holder force throughout the punch stroke, the sheet tension can be varied arbitrarily (Ref 120–122). Alternatively, special

reverse-bending tooling may be devised either for pure bending (Ref 123, 124) or in the context of a more general channel forming (Ref 73, 125).

More general empirical approaches based on observations of numerous forming operations (Ref 126–129) involve a range of options including altering  $R/t$ , die clearances, punch bottoming, coining, and off-axis/in-plane compression.

**Compensation of Springback.** Instead of trying to reduce springback, which invokes penalties in formability, an alternative approach is to design dies that produce the desired final part shape after springback. (Usually, the die face for a sheet-formed part is very close to the desired part shape; therefore, springback moves the final part configuration away from the desired one.)

If springback prediction is considered a forward analysis, then a backward analysis is needed to use such results to modify a die design in order to achieve a given final part shape. For simple bending operations involving constant radii of curvature, dies can be designed to account for springback using handbook tables or closed-form solutions, which can be inverted to specify tool radii for desired final-part radii. For new or unusual materials, varying radii of curvature (i.e., arbitrary curves), or arbitrary or

3-D shapes (with compound curvature), spring-back compensation has traditionally been carried out by simple trial and error or some variation thereof (Ref 130–132). Unfortunately, this procedure often produces unsatisfactory results and depends intimately on the skill and experience of the user. The process can take many months, thus extending critical tooling lead times. The trial-and-error method can be applied using FE forward analysis trials instead of experiments, but the backward design steps are equally inefficient and may take a similar amount of time.

Schemes for guiding the forward and backward analyses may be found in the literature based on various optimization strategies (Ref 89, 133, 134). These methods typically involve a gradient calculation and sensitivity analyses. Considerable complexity in formulation and implementation is involved, and usually special programming within special-purpose FE programs is required.

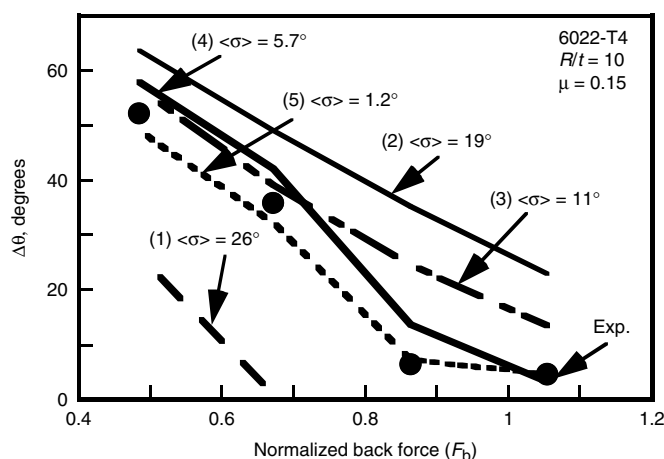

A promising approach integrating forward (FE) and backward analyses in an iterative scheme was reported by Karafilis and Boyce

(Ref 135–137). This method, denoted the spring-forward method, may in principle be used with any FE program. As discussed subsequently, however, its application suffers from lack of convergence (Ref 138, 139) unless the forming operation is symmetric or has very limited geometric change during springback (Ref 138).

Figure 27 outlines the steps of the spring-forward method. A flat sheet is first deformed into the target shape, and the external forces are recorded. At step 3, the target shape is elastically

#### Steps

**Fig. 27** Schematic representation of the steps undertaken in the springforward method of springback compensation. Step 1: flat sheet before deformation; Step 2: form to the tool shape and record external force field; Step 3: apply the recorded force field to the previous tooling shape and obtain the new tooling shape; Step 4: evaluate the  $(i + 1)^{th}$  tooling shape by comparing the part shape, after forming and springback, with the target shape.  $\vec{x}_{tool}^i$ , forming tool position at  $i^{th}$  iteration;  $\vec{F}$ , force. Source: Ref 135–137

**Fig. 28** Schematic representation of the steps undertaken in the Displacement Adjustment method of springback compensation. Step 1: form the part to the  $i^{\text{th}}$  tooling shape; Step 2: compare the part shape after springback with the target shape; Step 3: generate the  $(i+1)^{\text{th}}$  tooling shape by adding the displacement error field to the  $i^{\text{th}}$  tooling,  $X_{\text{tool}}^i$ , forming tool position at  $i^{\text{th}}$  iteration;  $\Delta y^i$ , the  $i^{\text{th}}$  displacement correction. Source: Ref 138

loaded by the recorded external forces, and the next trial die shape is obtained (the same shape as the deformed blank at the end of this step). This is the springforward step. The accuracy of the trial die shape is next checked by doing a forming and springback simulation. If the resulting springback shape is not the same as the target, another cycle will be carried out from step 1. Now, a flat sheet is deformed to the trial die shape just obtained, instead of being deformed to the target shape as in the first cycle. External forces are recorded and applied to the target shape. A new trial die shape will be obtained. The new trial die shape will be checked again at step 4, and iterations will continue until the target part shape is attained within a specified tolerance. Variations of this approach have been presented making use of internal forces instead of contact forces (Ref 137).

An alternate iterative design method that avoids many of the limitations of springforward while maintaining its generality and ease of implementation may be designated the displacement adjustment method (Ref 138). Instead of a springforward step using simulated contact forces, the simulated forming and springback displacements are used to predict the next die design iteration. A similar approach has been used in one-step simulation versions (Ref 140) and via experimental iteration (Ref 67, 141). The displacement adjustment method appears to offer several advantages over the springforward method, including excellent convergence rate, ease of implementation, and considerable generality. However, it has only been tested for rather simple 2-D, bending-dominated problems as of this writing.

The displacement adjustment method is outlined in Fig. 28. First, a flat sheet of metal is deformed to a trial die shape (for the first cycle, the trial die shape is the target shape). After springback, the springback shape is compared with its target. The shape error is defined as  $\Delta \vec{y}^i$ , which is the vector difference of coordinates of a FE node in the springback shape and in the target shape, at the  $i^{\text{th}}$  iteration. At step 3, the  $\Delta \vec{y}^i$  is added to the current die shape nodal positions, obtaining a new tooling shape of  $\vec{X}_{\text{tool}}^{i+1}$ . For the next cycle, a flat sheet is deformed to this new tooling shape. If the springback shape is not within a specified tolerance of the target (checked at step 2), another iteration will be conducted.

Comparison of springforward and displacement adjustment methods for a simple bending-dominated forming operation have been presented (Ref 138). For an arbitrary, nonsymmetric, nonconstant-radius part shape (Ref 138), both methods were applied, with iterative results shown in Fig. 29. The normalized error for the  $n^{\text{th}}$  iteration cycle in Fig. 29 is defined as:

$$\frac{\text{rms error}^{(n)}}{\text{rms error}^{(1)}} \quad (\text{Eq 63})$$

where:

$$\text{rms error} = \left[ \frac{\sum \Delta \vec{y}_k^2}{N} \right]^{1/2} \quad (\text{Eq 64})$$

where rms is root mean square,  $K$  is a counting variable that progresses from 1 to  $N$ , and  $N$  is the total number of nodes of displacement.

Analysis of simpler, symmetric operations showed that the obstacle to applying the

**Fig. 29** Convergence and accuracy comparison of springforward and displacement adjustment (DA) springback compensation

springforward method lies with the unknown constraints that must be enforced during the springforward step to restrict rigid body motion. Unless such conditions are applied at exactly the right location, which usually is unknown for a general problem, the springforward forces distort the workpiece and lead to nonconvergence of the technique.

## ACKNOWLEDGMENTS

The authors would like to thank the funding support of the National Science Foundation (DMR 0139045) and the Center for Advanced Materials and Manufacturing of Automotive Components at The Ohio State University. Computer simulations were conducted with the help of the Ohio Supercomputer Center (PAS080). Special thanks to Christine Putnam, who helped prepare the manuscript.

# CAD/CAM and Die Face Design in Sheet Metal Forming

Ed Herman, Creative Concepts Company, Inc.  
Daniel J. Schaeffler and Evan J. Vineberg, Engineering Quality Solutions, Inc.

SINCE THE EARLY 1980s, ever-evolving computer technology and processing speed have brought about revolutionary changes to the sheet metal forming industry, beginning with the development of computer-aided design (CAD) and computer-aided manufacturing (CAM) capabilities and continuing currently with the development of computer-aided engineering (CAE) tools to facilitate the application of physics and mathematics in the process of part and die design. These changes have taken the industry from a purely art form to the art/science form that it is today (2006). The sheet metal forming industry is now poised for the next step of going to a truly engineering form, where the meaning of CAE will incorporate true syntheses of design as well as analysis (as it now does) and optimization (as is starting to show up in limited forms). (Computer-aided engineering is discussed in more detail in the article "Process Modeling and Simulation for Sheet Forming of Steel" in this Volume.)

Critical in providing the infrastructure needed for the computerized "science" in use today 2006 and for the computerized "engineering" of the future is the need for better descriptions of material properties—not better materials, but a better/different approach to materials characterization based on the traditional mechanical properties. Furthermore, an expanded understanding of the role of friction is needed, along with the proper techniques to apply this knowledge to the die development and simulation process.

With a significant portion of the die development process occurring with the aid of computers, it is imperative that the files used are complete and that appropriate information can be exchanged between them. The CAD data for product and manufacturing should include files that contain the geometry of the sheet metal in all stages of production and use, plus files that contain the geometry of the actual die faces (addendum, binder shape, and die wrap). Creating these die face files is called functionalizing the die face. Once functionalized in the CAD system, the die construction and tryout costs are significantly reduced.

This article includes the following sections:

- Grade designations
- Materials specifications
- Forming limit curve
- Friction (draw bead, binder, and internal die radii)
- Product development process
- Direct engineering for formability
- CAD data sets

## Grade Designations

Sheet steels for draw forming are typically sold under grade designations that are generally indicative of their relative strengths and formability or how they achieve their strength. Typical grades include:

- Lower-strength steels, including commercial steel, forming steel, drawing steel, deep drawing steel, and extra-deep-drawing steel (also known as interstitial-free steel)
- Medium-strength steels, including bake-hardenable steel, interstitial free-rephosphorized, and carbon-manganese steel
- Higher-strength steels, including high-strength low-alloy steel, dual-phase (DP) steel, transformation-induced plasticity (TRIP) steel, and others. DP and TRIP steels are part of a family of steels collectively known as Advanced high strength steels (AHSS). For more information on AHSS, see the article "Forming of Advanced High-Strength Steels" in this Volume and Ref 1 to 5.

Such specifications as SAE 1008 and 1010 cover chemistry requirements only and do not have any minimum mechanical property requirements. Some minimum mechanical property requirements are listed in SAE J2329 (lower-strength steels) and SAE J2340 (for some medium- and higher-strength steels). The Society of Automotive Engineers is also developing a specification to cover the AHSS grades (tentatively designated as SAE J2745). However, these specifications typically list only minimum and maximum values for yield strength, with

minimums only on tensile strength, elongation,  $n$ -value, and  $r$ -value.

The stress-strain curves and the range of variation of those curves for the actual material produced by any one mill will vary somewhat from those of other steel mills. To some extent, this is true even for different mills within one steel company. The industry practice for making new dies work is to tune them in to the material from the mill that will be supplying the steel. Naturally, the tuning process ends when the die just works, that is, when the first "safe" part is achieved. It is common for dies to not work well with material from any other mill.

To make the dies robust to the normal and reasonable variation of the material is to design the dies to be robust to that variation rather than to "just get them to work." Such designs were impossible in the past, but now that computer simulation and direct engineering are available, such design objectives are at least technically feasible. The practicality of creating such designs is still not perceived by the industry as realistic but must be made so if the full utility of the materials and the stamping processes are to be realized. A major reason why the robust die designs are not being created today (2006) is that the designers and formability engineers do not have the data of the range of variation of the materials (as illustrated in Fig. 1), reiterating the need for this information.

Material characteristics that are used in defining a sheet metal grade include but are not limited to:

- Tensile stress-strain curve
- Forming limit curve
- Minimum and maximum yield strengths
- Minimum tensile strengths
- Minimum, or typical, total elongations
- Minimum, or typical,  $n$ -values
- Minimum, or typical,  $r$ -bar values, as well as their directional components ( $r_0$ ,  $r_{45}$ , and  $r_{90}$ )
- Thickness tolerances (Present standard tolerances should be revisited.)
- Crown limit
- Surface roughness

## Materials Specifications

Historically, the stamping industry has pressured the materials suppliers for “better” materials. “Better steel” has different meaning to the product engineer than to the manufacturing engineer. The product engineer is usually trying to get higher strength (e.g., yield strength) at low cost so he can reduce the gage and save weight. At the same time, he needs good formability so his designs can be formed into the shapes he needs. The manufacturing engineer is looking for better formability and more consistency in forming performance. The manufacturing people are periodically faced with situations where one batch of steel works in the dies and another batch will not work. Yet, both meet the specifications for the steel and satisfies the requirements on the purchase order. The reason one coil will work and another will not work is the normal and reasonable variation in even sequential coils of sheet metal, as illustrated in Fig. 1, and the die creation process. The die creation process often does not allow time, money, or even the possibility of testing the die for the entire range of material variation during the die design simulation or the physical die try-out stages.

Exactly how the material will perform in the dies is not known until the part design is completed, a die face is designed, and the operation of the die on the material is simulated. Even then, designs that work in the simulation may not work with every coil of steel supplied to the specification. Unless simulations are made to study the behavior for the total range of reasonable and normal variation of the material, the design may not be robust to that total range of properties, and some coils of material will not work in the dies. The same can be said for the variation in friction between the sheet metal and the die. Today (2006), it is possible to explore the robustness of the part/die designs throughout the range of variation with computer simulations. Such sensitivity studies are not yet common practice but are starting to be used. Not only do such explorations take more time and computing costs, but the necessary information for the material

**Fig. 1** The stress-strain curves for consecutive coils of steel for a single grade of steel, illustrating that no two are alike. The parts and the dies must be designed to be sufficiently robust to handle such normal and reasonable variation.

and friction is generally not available. At best, the analysis uses typical values (or what the analyst considers to be worst-case values) for both the material behavior and the friction and then adjusts to be (hopefully) conservative. By being conservative, failures are minimized, but optimal use of the material is not necessarily realized. There is a tendency to err on the side of requiring unnecessary design changes rather than risk production failures.

There is considerable opportunity for the materials supplier industry to better support the available engineering calculations that are in use today (2006). (Future advances in product and die engineering calculations will also need the materials performance information being suggested here.) Such improved support is not just in creating “better” materials but in providing more descriptive data and standards for existing materials. One way would be to provide the bounding stress-strain curves defining the six-sigma normal and reasonable variation of the material falling within each grade designation, as illustrated in Fig. 2, in addition to the specified properties listed previously. These bounding curves may not be actual data for any specific piece of material but rather composite curves created to bound the variation. These bounding curves are in addition to the average and standard deviation of the yield and tensile strength, elongation,  $r$ -value, and  $n$ -values. Another improvement would be to specify the maximum and minimum values for each of the properties listed previously instead of just minimum or typical values.

The stress-strain curve for most sheet draw forming materials is commonly represented by what is called the power-law relation:

$$\sigma = K(\epsilon_0 + \epsilon_i)^n$$

where  $\sigma$  is the true stress,  $K$  is the extrapolated true stress at a true strain of 1.00,  $\epsilon_i$  is the instantaneous true strain,  $\epsilon_0$  is the strain offset to get the 0.002 strain offset yield stress to hit the power-law stress-strain curve (The  $\epsilon_0$  can be considered the equivalent strain induced by the steel processing to achieve a specified yield stress.), and  $n$  is the strain-hardening exponent.

**Fig. 2** Bounding curves for a specific material grade. Any specific grade of material should be defined by two stress-strain curves that describe the plus/minus three-sigma boundaries of normal and reasonable variation.

Some argue that the power law is insufficient to represent all materials well enough and they fit the stress-strain curve with other equation forms and other coefficients. This argument is particularly relevant for sheet aluminum and the advanced high-strength steels such as DP and TRIP steels. Although these discrepancies exist, the error is insignificant when compared to the noise of variation from coil to coil of material. Because a design must be robust to the total spectrum of normal and reasonable variation, the power law is therefore quite adequate. However, a practical resolution may be for the suppliers to provide both the stress-strain curves and the coefficients that give the best power-law fit. From the power-law coefficients, the user can recreate the stress-strain curves. Or, if the user prefers, he/she can fit another equation that he/she feels is more appropriate to the supplied curves. The user can also simply digitize a number of points on the curve and interpolate between the points.

To use the engineering computational capability available and practical today (2006) for both product and die engineering, the engineer must be able to reconstruct the stress-strain curve and compute the stress that results from any strain, and vice versa. Therefore, the material behavior must be provided to him.

## Forming Limit Curve

Another very useful representation of the material is the forming limit curve. The stress-strain curve from a tensile test, described previously and in Fig. 1 and 2, represents the behavior of the material in a single mode of deformation. It is pulled in one direction only, and the thickness and width of the pulled specimen are unrestrained. As the material is being formed into a real part in a real die, the material is deformed by external forces pulling or pushing on the material in all three directions. The forming limit curve, shown in Fig. 3, captures the necking failure limit of the material through all the common deformation modes. Fortunately, for low-carbon steels, the FLC<sub>0</sub> point (the lowest point on the forming limit curve, or FLC) can be estimated from the  $n$ -value and the thickness of the material, and the shape of the curve remains the same. However, that simple relationship does not hold true for other materials, such as aluminum and stainless steel, and it may not hold true for all steels in the emerging range of new products, such as TRIP steels.

The conventional strain-based FLC is created by stretching various-width strips of material over a smooth ball. The ball is large enough so that relatively little stress is introduced through the thickness of the material. The result is that the material is strained proportionately throughout the test. What is meant by a proportional, or linear, strain path is that halfway through the test, the strip will be stretched half of its final lengthwise strain and will have half of its final

width strain. This strain-based FLC is relevant only to those forming processes that result in a linear strain path. Fortunately, most first-draw forming operations impart nearly proportional strain paths, so the discrepancy between the simulation result and the failure criteria is not considered to be a serious issue. Most computer simulation programs actually track the strain path to determine/predict the final strain conditions throughout the formed part. Those final strains are then compared to the strain-based FLC to show where the material may split, where it is dangerously close to splitting, and where it may wrinkle under certain part geometries and material flow conditions.

However, a nonlinear strain path may be found in secondary forming processes, such as some restrike operations, and even in some areas of the first-draw die, like re-entrant surfaces such as door handles on doors that have been subjected to high prestrain. In these cases, because the strain paths significantly differ from the ones used to form each point on the linear strain path strain-based FLC, that FLC is not applicable. Recent work (Ref 6–10) has shown that there is a corresponding stress-based FLC, and this stress-based FLC is independent of the strain path and is unique for a given material, such as steel or aluminum (Ref 11). Using a stress-based FLC resolves the discrepancy of calculating strains that result from nonuniform strain paths and then evaluating the risk of failure (i.e., splitting/breaking) by comparing those strains to proportional strain path failure data (i.e., the strain-based FLC).

The stress-based FLC is a relatively new approach to refine formability theory. When a new material or grade is made available to the manufacturing industry, the FLC for that material must also be provided. Conventionally, the strain-based FLC was generated, but the merits of stress-based FLCs are helping this approach to gain acceptance.

**Fig. 3** The forming limit diagram. In real forming operation, the material experiences stretching in both directions, as illustrated by the “Stretch” circle; stretching in only one direction, as illustrated by the “Plane strain” circle; or stretching in one direction while reducing in the other direction, as illustrated by the “Draw” circle. The forming limit shows the conditions at which the material will start to neck, after which it will soon fracture. For most low-carbon sheet steels, the  $FLC_0$  point (the lowest point on the forming limit curve, or FLC) can be calculated from the sheet thickness and  $n$ -value. The shape of the forming limit curve remains the same. It is moved up or down on the graph to fit to the  $FLC_0$  point.

The FLC is also extensively used to assess the strain safety status (“healthiness” or robustness) of an actual formed sheet metal panel. Before forming in the die, the blank is gridded with a pattern of etched and stained circles of a precise and known diameter. After the gridded panel is formed in the die, the circles have been deformed into ellipses (Fig. 3). These ellipses are measured and the applied strains plotted on the forming limit diagram. Any plotted points that are above the FLC indicate conditions that are likely to split. Those locations that plot too close to the FLC (i.e., in the marginal zone) indicate conditions that are likely to split should the material or process change. Only those locations that plot sufficiently below the FLC are considered safe in terms of formability. More details on how to perform a strain analysis and relate the data to a forming limit diagram can be found in the articles “Formability Testing of Sheet Metals” and “Troubleshooting Formability Problems Using Strain Analysis” in this Volume.

Once the bounding curves, as illustrated in Fig. 2, are generated for a particular grade from a given supplier, they can then be widened to encompass the normal and reasonable variation of the materials as available in the industry, as illustrated in Fig. 4. Such standards would not be more restrictive than what is produced today (2006) but would simply quantify what is being produced and supplied in a way that the user can optimize the use of the material.

## Friction

One of the least understood and most significant factors in sheet metal forming is the role of friction between the sheet metal and the die as the metal slides across the die face as the part is being formed. The advent of computer simulation and the future direct-engineering methods have provided the ability to put the effects of friction into the part and die designs mathematically. The problem (circa 2006) is that the effects are not well quantified. The practical approach has been to adjust a single friction coefficient used in the analysis until the analysis matches well a known condition, and then use that coefficient for future analyses. As with material properties, analysts have tended to err on the side of conservative friction values.

**Fig. 4** Bounding curves for different grades. Each grade of draw forming sheet metal (e.g., steel or aluminum) should have the stress-strain bounding curves. The properties of grades probably will overlap, as illustrated here. Any coil with properties outside the bounding curves could not be considered to be that grade.

There are three separate frictional conditions acting in a draw die. These are (1) the metal passing through a draw bead, (2) the metal clamped in the binder, and (3) the metal sliding across a die radius while it is simultaneously changing the wrap angle on the radius and is being increasingly plastically strained.

**The draw bead,** illustrated in Fig. 5, has been the object of the greatest investigative effort. Several physical draw bead simulators exist, and many data have been extracted from them and many papers written on those investigations. However, the draw bead performance of specific materials with specific lubricants has not been published as any type of accepted, and greatly needed, industry standard.

The amount of restraining force generated by a draw bead is a function of the sheet material being pulled through it, the lubricant, the die condition (e.g., material roughness, etc.), and the dimensions, depth ( $D$ ) and width ( $W$ ), of the bead. For any specific set of material, die condition, dimension  $W$ , and lubricant, the restraining force as a function of dimension  $D$  can be established in the laboratory by experimentation with a draw bead simulator (DBS). The results are illustrated in Fig. 6.

The bead restraining force is not used in the direct engineering of the die design. This

**Fig. 5** Draw bead. The draw bead creates a restraining force on the metal as it slides through the binder into the die cavity by bending, unbending, and friction as it is pulled through three (or four) radii ( $R$ ).  $D$ , depth;  $W$ , width

**Fig. 6** Effect of depth on draw bead restraining force. The draw bead restraining force is nearly proportional to the depth until the maximum depth of twice the bead radius ( $R$ ) is approached. As the bead depth exceeds twice the radius, no additional restraining force is generated.

analytical technique inputs (or calculates) the restraining force. The bead force is used after the design has been finalized to determine the bead geometry that will create the calculated required restraining force. That geometry is then built into the CAD data files for the die face.

There are several draw bead computer models in use today (2006). Some of these are commercially available, and some are proprietary. These models allow interpolation between, and extrapolation beyond, actual test data to provide bead performance data on a wide range of conditions. For these models to work correctly, they must be supplied with the bead geometry, the material performance data (as described previously), and the friction for the die, material, and lubricant combination. The friction values are calculated from the DBS test data. These friction values represent a complex and low-pressure condition, and it can be argued that the values calculated by the normal methods are not true friction coefficients but rather some combined friction coefficient and error correction factor. The use of the friction coefficients is valid as long as the coefficients are used for the friction models and are not used for other conditions (described subsequently) that exist in the die.

**The binder** is that section of the die outside the part that first clamps the sheet metal before the punch enters and stretches the sheet metal into the part shape. The binder serves several functions. The first is to preform the sheet into a developable shape that places, to the best possible extent, the right amounts of material into the right areas for subsequent forming. The second function is to keep the sheet metal within the binder from wrinkling. The third function is to create the necessary backforce for properly forming the part as the punch stretches it into the desired shape. A part of that third function is to be the mounting platform for the draw bead.

As the sheet metal is stretched in the generally horizontal part area to set the part shape into the sheet metal, some of the extra metal (from stretching) will move (displace) into the more generally vertical stretch or draw wall between the part area and the binder, as indicated by the diverging arrows in the part area shown in Fig. 7. Similarly, any metal being pulled (drawn) from the binder into the stretch or draw wall will result in hoop compression, as indicated by the converging arrows in the binder area shown in Fig. 7. Two elements of sheet metal in the binder area located at points A and B, respectively, will move to points A' and B', respectively, causing them to become closer together. The material between the two elements must do some combination of:

- Be compressed and thicken
- Become elongated in the direction of the arrows by having sufficient pulling force in the direction of the arrows to plastically deform the material to the uniaxial tension condition or greater
- Wrinkle

One purpose of the binder is to control the wrinkling to within some allowable amount (what is allowable can vary from application to application) and thereby force some combination of the other two possibilities into the sheet metal.

The binder should not actually clamp the sheet metal. Instead, the binder should be closed onto blocks outside of the sheet metal and those blocks hold the binder open from the sheet metal by approximately one-fourth of the metal thickness. The binder should be held onto the blocks with sufficient force that the metal can not push it off the blocks as the metal starts to wrinkle. Although the metal will wrinkle slightly, it can not wrinkle as much as the displacement arrows imply. Hence, the material must plastically deform.

If that deformation can be represented by a circle that is deformed into an ellipse, the largest diameter of the ellipse (the major strain axis) is aligned in the direction of the displacement arrow. The plastic deformation of the material (one can think of this as rearranging the surface area) requires a pulling force on the metal in the direction of the displacement arrow that is equal to a force in the opposite direction restraining the sliding motion. The slight wrinkling of the metal creates a normal force on the binder that is a function of the material internal resistance to deformation, the material thickness, and the height of the wrinkle. The friction between the metal and the binder is small but can still generate a significant force acting to restrain (but not stop) the sliding motion of the material through the binder and toward the part being formed. The friction-induced restraining force is additive to the plastic deformation restraining force. Figure 8 is a view of the section from Fig. 7 and illustrates the wrinkling that occurs as a result of the converging material displacements in the binder. When more force is needed to adequately restrain the sliding motion of the material, draw beads are added.

The friction coefficients representative of what is happening in the binder can be measured by pulling strips of material through flat

**Fig. 7** Effect of a binder on sheet metal behavior. As the sheet metal blank is drawn into a part shape, the material that forms the part shape is generally stretched outward, and the material within the binder slides inward, as indicated by the arrows. The converging pattern of the inwardly sliding material in the blank implies that the material will try to wrinkle.

plates. Such friction tests are available and should be used to generate the data. These conditions are very low-pressure situations, and the data should not be used for the internal areas of the die where the pressures and the metal straining conditions are much more severe.

**Internal Die Radii.** The third and most complex friction condition is where material is sliding across the curved punch and/or die faces and simultaneously being stretched in plastic deformation. The condition is illustrated in Fig. 9. The pressure of the sheet metal against the die face is a function of the radius and the stress in the metal and is calculated with the pressure vessel equation:

$$\text{Pressure} = \text{Instantaneous stress in the metal} \\ \times (\text{Metal thickness/Die radius})$$

The equation shows frictional restraining force to be small when the die radius-to-metal-thickness ratio is large (e.g., >15) but can be quite large when the radius-to-thickness ratio is small (e.g., <5).

The actual value of the restraining force is a function of:

- Die radius
- Included arc angle
- Amount of straining in the sheet metal

**Fig. 8** Detail of binder effect. As the material wrinkles, it bumps against the binder in this view of the section cut from Fig. 7. The binder limits the height of the wrinkle and withstands the force of the material pushing against it. The force vector diagram within the material illustrates the force component pushing on the die.

**Fig. 9** Force acting to restrain the sliding motion generated by friction and bending as sheet metal slides across a die face. The magnitude of that force is strongly affected by the radius and wrap angle.

- Stress in the sheet metal in the direction of motion
- Velocity of the sheet metal relative to the die
- Displacement distance (separate from velocity)
- Die material and coating (e.g., chrome plating)
- Die surface finish
- Lubricant type
- Lubricant amount

The value also depends on interactions between these factors. In the late 1990s, a team at the General Motors Metal Fabricating Division created a friction test that captured the global effects of the conditions by having the die radius on a separate block resting on load cells. This work showed the variability of friction and the ability to accurately measure it at actual press speeds and with large specimens. The test equipment, procedure, and results of that work are included in the final report of the National Institute of Standards and Technology (NIST) Springback Predictability Project (Ref 12). Such a test measures the combined effects of friction and the forces necessary to accomplish the bending and unbending. To reduce the data to just friction, several data-processing steps are required. First, the test must be modeled by the simulation program in which the test data are going to be used. That simulation modeling of the test is done with the friction value set to zero and the simulation post processed to output the same data curves as derived from the actual test. These curves simulate the zero friction condition, so they represent what the test data would be if there was no friction. Thus, these simulations show what the simulation code would predict for only the effects of bending and unbending. Then, the difference between the simulation data curves and the actual data collected can be mathematically analyzed to deduce the friction values. The difference between the simulation and the test data is a value that includes the friction and is also a correction for any errors in how the simulation software computes the bending contributions. Because the various simulation software programs have different methods of computing bending and different interpretations of how friction is applied, the adaptation of the test data must be done for each simulation package. The results of the test data must be reduced by regression analysis to coefficients of a basic equation. The form of the basic equation can be standardized, and a set of coefficients can be created for each sheet material, die material, die coating, and lubricant combination. Such data should be created and made available as an industry standard.

The NIST Springback Predictability Project, completed in 2000, also enhanced the LS-DYNA (Livermore Software Technology Corp.) software package to enable the program to work with the user's friction models at every node and time step, to ensure the use of the correct friction factor at all times and at all locations during the simulation.

## Product Development Process

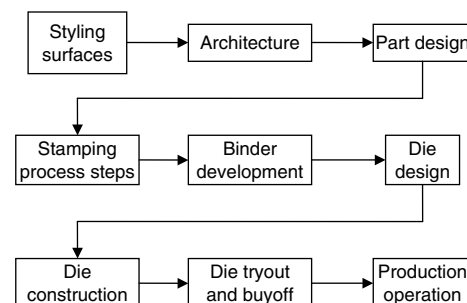

As an automobile is conceived and the engineering data created, the data forms go through many stages. The automobile example is used here because it represents one of the most complex situations. Other situations will usually be some subset of what is described here. The following descriptions of vehicle development only apply to those portions of the vehicle development process relating to the stamped sheet metal components. The basic steps in the vehicle development process are shown in Fig. 10.

The objective is to design the part, the die, and the stamping process to fully use the capability of the material. Both simulation and direct engineering are used in the binder development step, shown in Fig. 10, to achieve that objective.

The die engineering community advises the product community as to the feasibility of the product geometry. For the most part, that advice is still experience based, as illustrated in Fig. 11(a). Even when the advice is in formally packaged standards or design guidelines, these standards and/or guidelines are created based on experience. As the industry moves into the future, such advice will be based more on actual calculation of the material's capability for each situation.

The processing steps and the draw die binder developments are also created from experience, as illustrated in Fig. 11(b). The shapes in the binder development are transferred into the die as the die faces, and therefore act to collect and focus the force and motion from the stamping press onto the sheet metal to change it into the formed part.

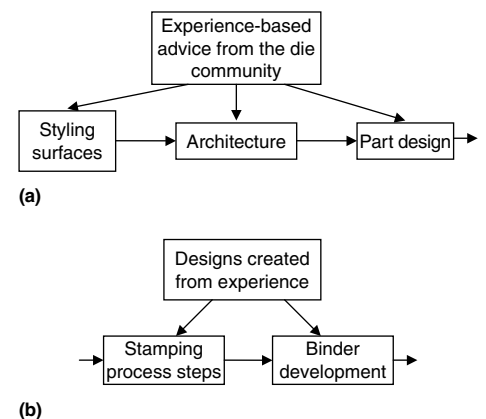

In the past, a die was built and then tried out (see the "Tryout and buyoff" step in Fig. 10) to determine if the experience-based design would actually form the material properly. The die was then physically modified until the part was free of splits and wrinkles. Today (2006), both the part and the binder development are created in CAD systems with the same experience-based inputs, which results in the same experience-based designs but in a math form. The performance of the die is now simulated in a computer (instead of being built), as illustrated in Fig. 12,

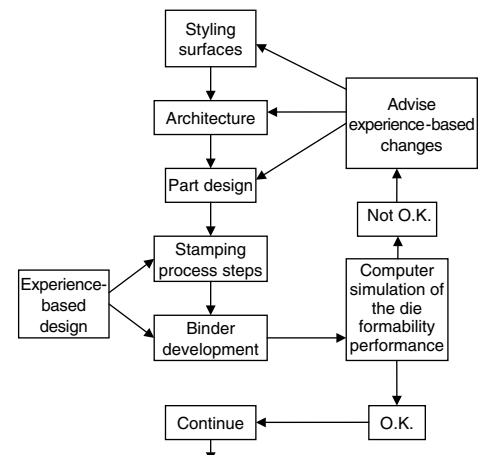

**Fig. 10** The basic steps in the creation of a stamped sheet metal part for an automobile. The steps shown are those where formability issues must be addressed in one form or another.

to determine if it will perform as desired. Any undesirable condition is modified, based on experience, and the new design is then simulated again. It must be noted at this point that the designer of the die binder now has a much faster and accurate learning experience, because of the computer simulations. The simulations give the designer much faster feedback on the performance of his design; he actually revises the design (instead of the try-out die maker), and the simulations give him much more information as to how the material failed.

Today's (2006) practice of computer simulation of the design performance introduces science and mathematics into the formability aspects of the die creation process and has

**Fig. 11** Experience-based product and die design. (a) Advice as to how the part geometry should be designed to accommodate the material formability is generally supplied to the product community by the die community but is experience based, and as such is neither scientific nor mathematical. (b) The die community creates the binder development (which defines the die faces and focuses energy onto the sheet metal to change it from what it is to what one wants it to be) by experienced judgment.

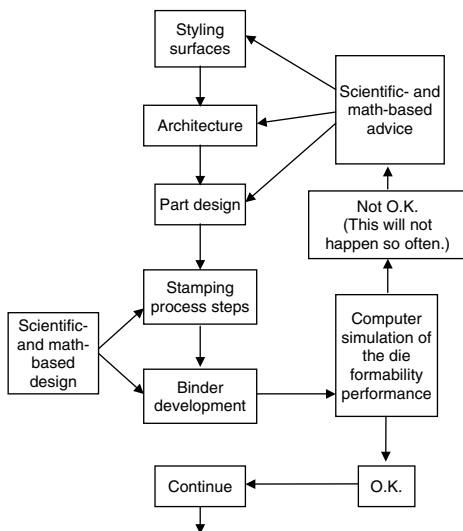

**Fig. 12** Use of computer simulations to test experience-based designs. Today (2006), the experience-based product and die face (i.e., binder development) designs are tried by computer simulation. Any undesirable condition discovered by the simulation is modified by experience and then tried again.

resulted in untold improvements in the cost, performance, and lead time of that process.

The future direct-engineering methods alluded to previously would facilitate the application of science- and math-based advice and design, as illustrated in Fig. 13. By applying in a direct-engineering (i.e., synthesis) approach, using the same formability science and math now used in the computer simulation codes, an optimized design will be created directly as it is being drafted. Such practice will result in better use of the materials and far fewer simulation-design iterations. Cost, quality, and lead time will be further reduced.

## Direct Engineering for Formability

As mentioned previously, the present method of creating product and die geometries and the sizing of those geometries is done by experience. The result is that the part and die designs are much the same as those done in prior times with manual designs and physical models, except they are now being done electronically with a CAD system in a computer. Those same CAD systems and computers now enable the application of the same science and math used in the finite element simulation programs to be used as the design (either product or die face\*) unfolds. The science and math can be used in a synthesis mode rather than just a postmortem analysis mode. The

**Fig. 13** Direct engineering. The future direct-engineering methods will change the experience-based advice-and-design practice shown in Fig. 12 to a scientific- and math-based practice, as shown here.

\*The phrase *die face* is used here to differentiate between the creation of the die surfaces that actually contact the sheet metal and the design of the rest of the die. Once the shape of the die face, the forces acting on it, and the relative motions of those surfaces have been determined, the metal thickness is the only property of the material that is of any concern to the design of the structural and mechanical die. The design of the rest of the die happens after the die face is created and entails considerably more work by a different group or person.

following is a simplified example to demonstrate the basic direct-engineering method. What makes the approach possible is the way the problem is structured.

**Direct-Engineering Method Example.** The example is a stylized engine hood for an automobile, as shown in Fig. 14. The design of the engine hood is provided, and the design to be completed is the die face, which consists of the addendum, binder shape, and binder wrap. For simplicity, only one section—through the hood—is used in the example, as shown in Fig. 15. An actual design of the die face (i.e., the binder development) for such an engine hood would require six to eight such sections plus a reconciliation of the binder wrap to all the “X” points. The objective here is to present the thought process for direct engineering (synthesis) but not to actually design the die face.

**Step 1.** The first step is to clearly define the design objectives. For a part such as the example, a normal set of objectives would be:

- No splitting of the sheet metal
- No wrinkling of the sheet metal
- No impact lines or skid marks
- No highs or lows
- No springback, flattening, crowning, or twist

Some objectives that may not be so common but could have significant economic consequences are:

- Robustness to all normal and reasonable material and processing variation
- Short die-change time (where the first part made after a die set is a good part)
- Work-hardening drawing steel (180 MPa, or 26 ksi, yield strength) to 350 MPa (51 ksi) yield strength on the vehicle
- Size consistency (to fit the panel to the subsequent dies in the process)

**Step 2.** This step is unique to all net shape processes. One characterizing aspect of the net shape processes is that there is not a direct cause-and-effect relationship between the processing variables and the product features. A ramification of that aspect of the processes is that there are no die features or press operating settings that

**Fig. 14** Plan view of a stylized automobile engine hood used to illustrate the direct-engineering design method. The design developed will be for the addendum, binder wrap, and binder for the section of analysis identified here and shown in Fig. 15.

relate directly to the aforementioned list of objectives. There are no splitting or wrinkling control knobs. There are controls for shut height, tonnage, lubrication, blank location, and so on. The controls have different physical meanings and different metrics than do the objective requirements of the part.

To work through the aforementioned dilemma, the product objectives must be redefined as changed conditions of one or more transformation characteristics. A transformation characteristic is a characteristic of the material that can be transformed into some different condition through the application of energy. The mathematical relationship between the application of energy and the change in condition is known, as is the mathematical relationship between the new condition and the product objective conditions. For sheet metal forming, the transformation characteristics are strains and displacements. Thus, critical and target strains must be specified and the displacement pattern and critical displacements identified.

The critical strains are the forming limit of the material (Fig. 3). Conventional use typically requires that all major and minor strain combinations must plot at least 10% lower on the major strain axis than the forming limit curve. This approach typically ensures that the first requirement (i.e., no splitting) will be met. The target strains are usually the smallest strains that must be achieved and the location of those strains. In the selected example, the target strains are driven by the need to work harden the material up to a yield strength of 350 MPa (51 ksi), and these strains must be obtained or slightly exceeded throughout the expanse of the engine hood.

First, it is necessary to calculate the strain required to work harden the formed panel to the desired yield strength of 350 MPa (51 ksi). This is done using a power-law approximation of the stress-strain curve, with the following inputs:

- $K = 560 \text{ MPa (81 ksi)}$
- $\epsilon_0 = 0.006$
- $n = 0.18$
- $R = 1.5$
- $t = 0.8 \text{ mm (0.03 in.)}$

**Fig. 15** Section of the automobile hood. The product shape (heavy line) is the section of analysis from Fig. 14 and is given as a simple 700 mm (28 in.) long arc through an angle of 5°. The addendum is shown in dotted lines as a parametric form consisting of  $R_1$ ,  $Y$ , and  $R_2$ , ending at point X, which must be sized. The length of the wrap (dashed line) must be determined and then curved as necessary to fit between the centerline and point X.

The material behavior is defined by the stress-strain curve and the  $R$ -value derived from tensile testing. The tensile test imposes a very special strain relationship, because there is a force applied to the testpiece in only one direction. In a real part, pulling forces are applied to each small local region of the sheet in two directions. Also, as shown previously for the friction test, there can be a compressive force applied through the thickness when the metal is sliding over a curved die or punch surface. These real-situation forces must be mathematically related back to the tensile stress-strain curve. The equations for that relationship are well established in the literature and are used in all simulation and synthesis codes. As an example, when the aforementioned material properties are used in the power law to calculate the pulling stress (all other stresses are zero) for 5% strain in the pulling direction, one obtains 325.15 MPa (47.16 ksi). That is also called the effective stress (which is related to measurements after biaxial deformation). The yield stress would compute to 183 MPa (26.5 ksi). The effective stress is what would be measured as the yield stress from a tensile test specimen extracted from the formed part. The following table shows several strain pairs that could happen on a real part to result in the same 325.15 MPa (47.16 ksi) of effective stress:

Minor strain, %	Major strain, %
-2.5	+4.37
-2.0	+4.32
-1.0	+4.01
0.0	+3.48
+1.0	+2.77
+1.5	+2.34
+1.94	+1.94

Although several strain pairs will work, equal strains in both directions were chosen for the example because the engine hood is relatively square, and it simplifies the example. Straining the panel by +3.5% in both directions (hood centerline and normal) results in a formed panel yield strength of 357.7 MPa (51.9 ksi), which is only slightly more than the 350 MPa (51 ksi) desired. Note that the line of analysis of the hood centerline and its normal direction may or may not be identical to the major/minor strain axis determined from actual circle grid measurements or the output of a simulation.

The target strains must be achieved throughout the panel, but the location at which they are assigned by the designer to be the boundary condition for his calculations is at the neutral line. For the engine hood example, the neutral line is the front-to-rear centerline. The definition of a neutral line is the location on the panel where the designer wants no sliding motion of the sheet metal across the line as the die forms the part. The stretching of the sheet metal will result in sliding motion away from the neutral line, and the resulting displacements increase with distance from the neutral line. For the engine hood example, the 3.5% stretching of the 700 mm (28 in.) width of half the hood will be 24.5 mm

(0.96 in.) (3.5% $\times$ 700 mm, or 28 in.) at the fender edge of the hood. For this example, those displacements will cause no problem with impact lines or skid marks as long as the centerline is maintained as a neutral line, hence satisfying two more objectives.

Highs, lows, flattening, overcrowning, twist, and size variation are all aspects of springback resulting from the elastic straining (i.e., shrinkage) that results from the relaxation of the forming stresses. The designer should review the forming stresses as the design progresses and ensure that the die face geometry and strain assignments do not result in stresses that will twist the part out of shape when they relax as the die opens.

True stresses in the direction along the line of analysis and normal (i.e., into and out of the drawing) to the line of analysis are the stresses that relax when the die opens. As these stresses relax, the part gets smaller with elastic strain. The amount of size change is very nearly equal to the ratio of these stresses to Young's modulus of the material times the length of the region of the part affected. If the forming stresses are not close to equal when they relax as the die opens, the part will warp out of shape. Such warping out of shape is generally referred to as springback. Technically, springback is the elastic relaxation of the forming stresses when the die releases the part. However, when that relaxation is proportional in all directions, it does not normally attract much attention. Sometimes, when the elastic relaxation is not proportional, the conflicting elastic strains balance forces before completely relaxing, and there will be residual stresses; thus, the full dimensional size change will not be realized. Adjacent forming stresses usually should be within 10% to avoid shape distortion of the stamping. A uniform shrinkage is readily accommodated by a simple global expansion of the die (similar to the shrinkage allowance built into casting molds) and is easy to calculate, but twisting and bending are difficult to predict and equally difficult to accommodate with compensating changes to the shape of the die. (See the article "Springback" in this Volume.)

The robustness of the design to normal and reasonable material and processing variation is maximized when the design can be formulated to provide lock beads instead of draw beads in the binder. When no metal slides through the beads, there is a minimum of variation in the resulting part. The design method should always incorporate a lock bead if at all possible.

**Step 3.** The designer must now determine if the sheet metal can be pulled on at the part perimeter with sufficient force to make the target strains happen at the neutral line and without having the material strain more than the critical strains anywhere. That pulling force is applied mathematically. The mechanics of how it will be accomplished come later. The section line of analysis for the product, as illustrated in Fig. 15, is approximated by a series of true arcs connected tangentially from the neutral line to the edge of the part. The illustration in Fig. 15 for the

engine hood example consists of a single such arc of 700 mm (28 in.) arc length and through 5° of arc angle.

The forming problem of the sheet metal being stretched over that arc of the die face is illustrated in Fig. 9. The forces to achieve bending and unbending plus the force to overcome friction must be added to the force to achieve the target strain to calculate the required pulling force at the part edge. This can be done by defining any two dimensions of the arc (i.e., radius, angle, or arc length), the coefficient of friction, and the normal strain (target strain) at the outside end of the arc (+3.5%, as previously determined). The bending and through-thickness stresses and the friction force values are then calculated to help the designer determine where the geometry is causing excessive restriction to the movement of the sheet metal across the die face, should there be a problem with strains approaching the critical strain limits. All of these calculations can be done with a spreadsheet application once the proper equations, material properties, and cell relationships are set up. In this example, such a spreadsheet program shows a 3.5% target strain, which is also the peak strain, and this should be small enough to cause no concern.

Note that most parts will have more than one arc representing the shape of the part between the neutral line and the edge of the part. The output of each arc must be used as the input to the next so that the part analysis can proceed to the edge of the part.

In summary, the designer can enter the problem as radii, angles, and/or arcs. Then, forces are calculated that will accomplish the bending and overcome friction. Finally, the amount of stretch in that segment is calculated, and the amount of wrap length that is needed to start with is determined.

**Step 4.** The task is now to determine the dimensions for the addendum shape, shown as  $R1$ ,  $R2$ , and  $Y$  in Fig. 15. The parametric addendum shape would usually have 11 segments for unfolding flanges and trimming reasons, but the three shown in Fig. 15 are essential for forming the part and adequate for showing how the design process works.

In the example, there is an accumulated displacement of 25.97 mm (1.02 in.) determined from the spreadsheet calculations, which means that approximately 26 mm (1 in.) of sheet metal will be stretched off the punch and out of the part. That material must be put somewhere. However, the 26 mm (1 in.) of material is sliding generally horizontally while the press is closing the die vertically. Hence, the 26 mm (1 in.) of material must be dragged across  $R1$  like a rope over a pulley. The  $R1$  is simply another arc in the sequence, so the output of the calculation for the 700 mm (28 in.) arc of the product is the input for the calculations of what will happen to the metal as it is pulled across  $R1$  and further stretched. The 80° of arc angle shown in Fig. 15 is the maximum arc angle for geometric and mechanical reasons. If there is a forming problem, that angle can be made smaller.

As an example, the designer can select a radius of 8 mm (0.32 in.) and an arc angle of  $70^\circ$ , which the spreadsheet calculations show to result in the maximum (i.e., peak) strain being only 15.55%. That peak strain is approximately halfway to the forming limit for the material, which looks perfectly safe. However, a 7 mm (0.28 in.) radius with the  $70^\circ$  angle is shown by the spreadsheet calculations to make the material split, as will a  $75^\circ$  angle with the 8 mm (0.32 in.) radius. The decision as to what the angle and radius must be depends on the designer's understanding of the precision of the die-making process and the ability to maintain the initial geometry of the die during the production life of the die. A general rule is to make the angle  $5^\circ$  smaller than the largest that will work, and to make the radii 1 mm (0.04 in.) larger than the smallest that will work. The maximum angle and the minimum radius that work should be those that work for all conditions within the range of reasonable and normal material and processing variation.

Using an 8 mm (0.32 in.) radius, a  $70^\circ$  arc angle, and a 15.55% peak strain, the spreadsheet calculation shows that there is an accumulated 29.7 mm (1.17 in.) of material sliding out of  $R1$  into  $Y$ . Of that, 3.7 mm (0.15 in.) is due to  $R1$  alone, added to the 26 mm (1.02 in.) stretched off the punch. That 29.7 mm (1.17 in.) of material will be subject to additional stretching once in  $Y$ . The opposing punch and die motions (shown by the die motion arrows in Fig. 15) cause stretching of the sheet metal in element  $Y$ . That stretching acts like a spring, generating the force to do all the work of stretching, bending, and overcoming friction throughout the sheet metal. Therefore, that element is called the stretch wall. All of the accumulated stretching of the arcs between the neutral line and the beginning of the stretch wall is used to make the stretch wall. (The total length of the line of analysis except for the stretch wall is the summation of the original individual arc lengths, each of which is stretched some delta length. The summation of these delta lengths is what is used to make the stretch wall.) The length of the stretch wall is not added into the accumulated wrap, and the actual length of the element in the die is subtracted from the accumulated displacement. If the arc length of the stretch wall is made to exactly equal the accumulated displacements, the accumulated displacement out of the stretch wall will be zero. If the stretch wall is longer than the accumulated displacements, the accumulated displacement out of the stretch wall will be the difference and will be negative. A negative displacement is draw-in.

To achieve the small negative displacement out of the stretch wall, the designer must specify the arc length to be greater than the total stretched length of the metal sliding into it. In the ongoing example, it can be calculated with the spreadsheet that the 29.7 mm (1.17 in.) of metal sliding into element  $Y$  would stretch to 34.73 mm (1.37 in.) while in element  $Y$ . As such, the designer can specify the element to be 35 mm (1.38 in.) long to obtain a  $-0.27$  mm

( $-0.01$  in.) of displacement out. By building the die to these dimensions, the designer is assured that a locking bead can be used and that he has achieved the objective of maximum robustness to material and processing variation.

Note that a small negative displacement (usually between  $-0.2$  and  $-0.5$  mm, or  $-0.008$  and  $-0.02$  in.) is required to ensure that a stretch die construction will work. To test if the negative displacement could be excessive, one can divide the amount (in the previous example, 0.27 mm, or 0.01 in.) by the total length of the analysis line, including the stretch wall (which is 744.77 mm, or 29.32 in., for the previous example), to get the extra average strain in the line, should the negative displacement not occur. For the previous example, that would be  $0.27/744.77$  (0.01/29.32) or 0.036%. This error strain can then be added to the "along line" strain assignment to determine if it could possibly cause failure at any segment.

**Step 5.** The last step is to establish  $R2$  and the binder shape. The parameter  $R2$  is just another arc in series with all the others. However, because the displacement entering it is negative, the forces required to achieve bending and to overcome friction are subtracted from the accumulated forces. In the example, the friction force is 51 N/mm (7.4 ksi). With a lock bead at point  $X$ , a force of 289.8 N/mm (42.03 ksi) will be generated at this location, which in turn will generate the desired centerline characteristics outlined in step 1 (e.g., work hardening to 350 MPa, or 51 ksi; no skid marks off the centerline; and no splitting). Because the dimensions for the shapes in the addendum are now calculated, point  $X$  (Fig. 15) can now be positioned in space on the die design.

Finally, it is necessary to calculate the length of the material that must be contained by the binder between point  $X$  and the neutral line, as indicated by the dashed wrap in Fig. 15, which is determined to be 715.36 mm (28.19 in.). As such, the binder must be shaped (curved) so the length of the sheet metal when the binder has closed on it is 715.36 mm (28.19 in.) between the neutral line and point  $X$ .

Similar calculations will also give the amount of draw-in and the required draw bead restraining stress if a lock bead proves not to be feasible.

Direct engineering to establish the dimensions and shapes of the die addendum and binder has been illustrated. That work is done before any investment in drafting on the CAD system. These dimensions are then drafted into a die face on the CAD system, and the resulting surfaces are then analyzed with a computer simulation. The simulation must be set to evaluate the blank size, draw-in amounts, and the bead restraining stresses determined using the direct-engineering methodology outlined here, all of which can be facilitated by a spreadsheet to automate the calculations. Simple dies, such as the engine hood example shown, should not require computer simulation.

**Spreadsheet Calculation Method.** All of the processes and calculations described

previously are based on a fundamental understanding of the mechanics of metal flow. No one calculation is overly challenging, but there are numerous steps requiring a detailed setup. This lends itself to using a spreadsheet program to facilitate the calculations.

One such program has been developed by one of the authors as part of a binder development training program. The product analysis and binder synthesis (PABS) program is a Microsoft Excel-based spreadsheet that makes these calculations easy. PABS is based on power-law material behavior and is organized to support problems as described in this section. It performs the mathematical calculations for converting between engineering and true stresses and strains, computing effective strains and stresses, determining the force necessary on a hypothetical strip of material (with user-specified thickness) in the direction of the section of interest, calculating the frictional restraining force with a pulley friction formulation, converting bending energy into a required pulling force, and decomposing the results into strains on the output side of the subject die radius. Then, the force output of one radius is the force input to the next. PABS also keeps track of the accumulated stretching of the material. The equations used are evident to the user, and the user can change the formulations if other equations better describe the conditions being evaluated. The values quoted throughout the preceding example were generated with the PABS program for illustrating the engineering method.

**Other Forming Situations.** Many forming issues/questions can be resolved by even simpler techniques. Almost any section through a sheet metal stamping can be divided into a series of S-shaped inflections, as illustrated in Fig. 16. The metal to the left of the inflection sits on and slides along the lower die face (left horizontal arrow), and the metal to the right of the inflection sits on and slides along the upper die face (right horizontal arrow). The metal passing through the inflection is being stretched by the opposing motion of the two die halves.

**Fig. 16** Any section through a sheet metal part is a series of S-shaped inflections, where the metal is sitting on and sliding across the die faces on each side of the inflection and being stretched through the inflection by the opposing motions of the two die halves.

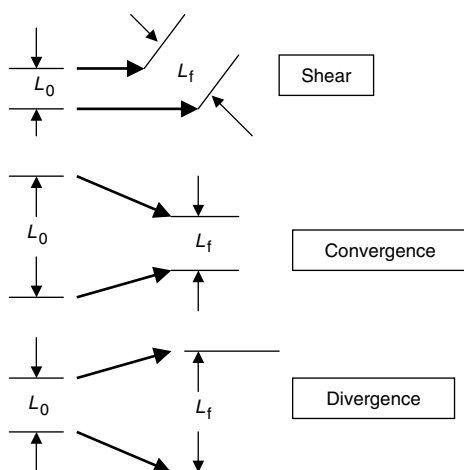

The length of material (length AB) through the inflection is often too long to be stretched from the available adjacent material (length A'B') in the wrap. The difference ( $D = AB - A'B'$ ) must be supplied from having material slide off one or both of the adjacent die faces, as indicated by the horizontal arrows. Because the lengths can be measured exactly in the CAD system, the amount of required displacement can be calculated exactly. In practice, both the left and the right horizontal arrows would then be drawn to the total length of the required displacement. Only one (or part of one and part of the other) would actually be used. The designer must decide which displacement best achieves the design intent. To decide, the displacement arrows of adjacent sections must be plotted to scale in the flat, and the resulting straining calculated, as illustrated in Fig. 17.

The resulting strains can then be plotted on a forming limit diagram (Fig. 3) and evaluated to determine if the locations are sufficiently safe. Then, a design decision can be made as to which displacement the die design should impose onto the material. The displacement thus determined becomes a target displacement for use in subsequent PABS calculations.

## CAD Data Sets

The CAD data must be created and maintained during the design process. The content and controls on each and the interrelationships between them must be clearly defined. Likewise, the hierarchy of the files, how the files are generated, and how they are used must be carefully established and understood by those using them. To maximize the benefits, industry standards on the nomenclature and content of such files are likely needed.

To begin with, the concept of CAD/CAM is inadequate for net shape parts. The concept was created when computer automation was focused

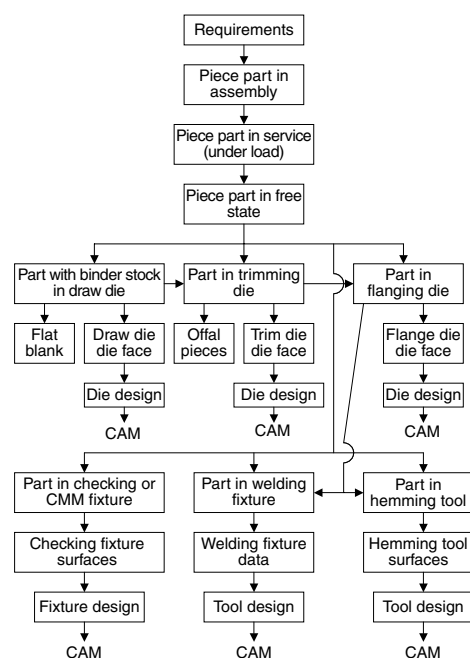

**Fig. 17** When adjacent arrows are plotted to scale in the flat, the necessary strains can be calculated by the measured distances between the heads and the tails of the arrows, where the strain is  $(L_f - L_0)/L_0$ .

on the machining of machined parts. For stamping, the concept must be expanded to CAD-CAD/CAM-CAM. The first CAD is the computer-aided design of the actual piece part—the stamping. The second CAD is the computer-aided design of the dies that make the part. The first CAM is the computer-aided machining of the dies that make the part. The second CAM is the computer-aided manufacturing (e.g., robot programming, automation programming, weld schedules) and inspection (i.e., coordinate-measuring machines) of the parts.

The hierarchy of CAD files may be as illustrated in Fig. 18. Data must flow from one data set to the next, as indicated by the arrows in the figure. Within each box, some, but not necessarily all, of the data arriving is used, and additional information is added. When the data leave the last CAD function, they go to a CAM function, such as computer-controlled machining, robot programming, or materials handling design. The nature of the data in some of the function boxes is discussed in the following sections.

When data from one CAD file are to be forwarded to another CAD function, the data should be filtered so that only those data needed by the receiving function are sent to it. Otherwise, the receiving function must sort through the data. Such sorting by the receiving function is usually inefficient, because the data are new to the receiving function, and that receiving function must study and understand the data before deciding what to use. Much of the reading and understanding is redundant work. The sending function is familiar with the data and can sort them much more efficiently. Also, much of the

**Fig. 18** Possible hierarchy of computer-aided design data sets for a typical automobile stamping. CMM, coordinate-measuring machine; CAM, computer-aided manufacturing

sorting could be automated within the CAD system.

**Requirements.** The requirements CAD file defines what the piece part must do and what it must not do. The requirements include but are not limited to:

- Forces that will act on the part
- The location at which the forces will act
- Limits on deflections resulting from the forces
- Vibration frequencies
- Styling surfaces to be incorporated
- Mechanical connections to other parts (e.g., bolting patterns)
- Surface finishes
- Other objects that the part must not interfere with
- Corrosion resistance
- Mass targets
- Other requirements

Many of the requirements are drawn to scale, while others are simply listed.

**Piece Part in Assembly.** Most parts are assembled together with other parts to make a consumer product. The stamping is one of the piece parts and must usually be shown as assembled with the other components of the consumer product.

**Piece Part in Service and in Free State.** In many instances, the subject piece part is put under some loading when assembled into the consumer product or when used as a component of the consumer product. These loadings cause the piece part (the stamping, in this case) to deform elastically, as illustrated in Fig. 19 for an automotive engine hood.

The design of the engine hood must be in the correct position relative to the rest of the vehicle when it has been deflected by the load imposed by the holddown latch and resisted by the outboard downstops. However, for it to end up in that position when the loading is imposed on it, it must be made to some specific overcrowned shape, as indicated by the phantom lines in Fig. 19. The overcrowned shape must be established by the product engineer, and that shape is what is manufactured. Except for springs, the design of the free-state part is skipped. In most instances, the part is sufficiently stiff that it can be considered a rigid body, and the consumer product will still work. However, the need to reduce mass and to minimize costs will force the consideration of the free versus stressed conditions.

**Fig. 19** Example of deformation in an automobile hood. The holddown latch force causes the engine hood to deflect when closed.

**Part with Binder Stock in Draw Die.** The piece of sheet metal from which the part is made is cut out of a coil. That blank can be rectangular, trapezoidal, or some developed shape, but it will be larger than the final part. Some of the extra material is the result of cutting from a coil that has parallel sides, and at least part of that exterior material comprises the binder area that is used to generate the pulling forces around the edge of the part that are necessary to stretch the sheet metal into the desired shape. The size and shape of that blank and the shape of the die faces outside of the actual part edge must be designed to impart those forces onto the sheet metal. The die shapes outside the part (and sometimes inside the part as well) are referred to as the binder development. Some of the final product shape may be out of position as it sits in the draw die when the die is closed on it. Those out-of-position regions are finish formed in subsequent dies. So, a CAD file must be made to define all of these geometries of the sheet metal.

Also, the draw forming operation imposes severe stresses into the sheet metal to form it. Then, when the die opens and releases the sheet metal, those stresses relax, and the sheet metal changes size and sometimes shape. It is the size and shape of the part defined by the free-state CAD files that must be achieved after this relaxation has occurred. Therefore, to compensate for the size and shape changes that result from this stress relaxation, the die (even in the product regions) must be designed and machined to a configuration that will be other than that defined in the free-state CAD file.

**Flat Blank.** A CAD file of the size and shape of the flat blank is required to build a blanking die, if one is needed, to calculate the material cost for the part and to specify the coil size to be purchased. (The blank may not be flat when the die has closed on it. That shape, whatever it is, is unfolded to the flat condition to determine the blank size and shape.)

**Die Face of Draw Die.** The previous CAD file was of the part as it is when the draw die is closed on it. However, that does not reflect what the shape of the draw die die faces should be. The die faces may not look much like the sheet metal. The die faces should only touch the sheet metal on one side at any location, but the surface that touches will change from side to side of the sheet metal, as illustrated in Fig. 20. Also, the die faces

**Fig. 20** Die conditioning in the forming of an automobile hood. The shape of the die faces (solid lines) may not follow the shape of the sheet metal (dashed lines), because the die should only touch the sheet metal on one side at any location.

must have additional surface features for runoff as the die face falls away from the sheet metal.

The die faces of the trimming and flanging dies must have offsets for trimming steel clearances, flanging material clearances, shear, trimming and flanging steel-to-nest bypass, and scrap cutters. These features are not reflected in the CAD file of the sheet metal sitting in the die.

**Offal Pieces.** It is easy to forget that the pieces cut off from the part in the trimming die (i.e., the offal pieces) must be managed after trimming. They must go somewhere and get away from the die. So, accurate CAD files of these pieces must be provided so that the proper materials handling of the offal can be designed and built.

**Die Design.** Once the die faces have been defined with CAD files, the die structure and mechanism can be designed. Each piece must be designed. Modern CAD systems use solid modeling so that the CAD files can drive cutter path programming directly. The die design must accommodate the fitting of the die to the press and integrate with the materials-handling automation.

**Other Tools and Fixtures.** Similar arguments and needs apply to all of the other tooling, such as the hemming tools, welding fixtures, and inspection fixtures. Welding CAD files are somewhat different in that only selected and small areas are extracted from the product surfaces for the locating and clamping points. Fixtures for spot welding need the  $x, y, z$  coordinates of each weld spot identified as a position in space, along with the surface normal vector of the weld gun alignment. Arc welding CAD files need the line to be welded and the surface normal for aligning the welding rod. The actual design of the fixture from this file is similar in functional concept to that for the dies, even though there is not similarity in appearance.

**Computer-Aided Manufacturing.** When a tool design CAD file arrives at the Computer Numerical Control machining station, the cutter path programmer should have no decisions as to what is to be made. He should only have to decide how to make it.

**Significance.** Significant efficiencies can be realized by having a proper hierarchy of CAD files and a clear understanding throughout the organization (and supplier community) as to what each file is called, what it contains, who is responsible for its content, and how it is to be used. As soon as these relationships between the data and the physical functionality are mixed up, enormous inefficiencies materialize.

This article places considerable emphasis on the need for the designer to clearly define the die/tooling faces in the CAD system before the data are passed on to the construction functions. This approach differs from what has typically been done. It has been the general practice to pass on to the tooling construction source only the design of the part as it sits in the closed die or tool. The tool or die builder (e.g., cutter path programmer) then must make many of the die/tool face functionalizing decisions and modify the CAD

data prior to programming the cutter paths. The suggested approach provides for a more controlled and consistent implementation of tooling and processing standards, eliminates a learning step, eliminates some sorting through of the data and the learning processes, and, in general, places the decision-making functions into engineering activities, where both the computer tools and the people's mind sets are more in line with the job functions.

# Computer-Aided Engineering in Sheet Metal Forming

Chung-Yeh Sa, General Motors

SHEET METAL FORMING is defined as deforming thin sheet metal (or tubes) into a useful shape by means of plastic deformation using a set of dies. It was a black art in real production until the 1980s. Many fundamental theories in plasticity had been published prior to this time. However, most application research work at the time was limited to simple shapes or idealized conditions. Hence, the direct impact of that work to practical applications in the industry was not very significant.

Computer-aided engineering (CAE) analysis using the finite element method was very successful in many different application areas in the 1980s. Unfortunately, the technology was not mature enough to be useful for daily production work until the mid-1990s. Since then, however, great progress has been made in this field. This article focuses mainly on the technology breakthroughs that make forming simulation a routine work throughout the industry.

## Background

**Industry Trends.** Since the dawn of the 21st century, the tool and die industry in developed regions such as North America has experienced several challenges that affect its ability to remain competitive in the marketplace. Among the most significant challenges are overcapacity, growing international competition, technology improvements, decreasing demand from automotive customers, and increasing pressure from customers to lower prices and expand services. Original equipment manufacturers (OEMs) and first-tier sheet metal parts suppliers have begun sourcing to low-cost producers around the world in recent years, which adds strong negative impact to the traditional tooling industry in developed countries. These challenges have resulted in many tool and die shops going out of business during the first few years of the new millennium.

To survive and remain competitive in the marketplace, tool and die makers have to adopt new practices, such as the lean manufacturing process, new technologies, and collaboration. These practices have been shown to result in

cost reduction and increased manufacturing performance. One innovative practice is the adoption of forming CAE to enable early evaluation of the product and die-face development. Proper implementation of this technology will help provide better cost estimation, lead time, and cost reduction, as well as help to meet quality and fast-to-market requirements. The CAE technology essentially replaces the traditional trial-and-error black art with scientific engineering calculations. Furthermore, tool and die makers can employ highly efficient and process-oriented tools to enable designers to use stamping CAE tools.

The aesthetics of automobile design have evolved dramatically, especially in the past 5 years. Modern vehicle designs embrace a more aerodynamic shape, with large sweeping curves, sharp features with tight radii, and retro styling with round but deep panels. The unveiling of these new designs turns what were once just futuristic concept cars into mainstream production vehicles. This trend brings many unknowns and challenges to the sheet metal industry.

Another challenge comes from an increased market demand for "green" (i.e., fuel efficient) vehicles with stringent safety criteria. This trend requires manufacturers to evaluate and use new materials for structural components and body panels. As a result, many new aluminum alloys and new advanced high-strength steel have been developed by metal suppliers and used by OEMs. The use of dual-phase, complex-phase, transformation-induced plasticity steels, and even ultrahigh-strength steel in the automotive industry has been increasing significantly in the last 10 years. These new materials are much stronger than the conventional mild steel (Fig. 1), thus allowing gage reduction while providing better crashworthiness.

Inevitably, the use of higher-strength steel leads to more challenges for traditional formability issues and dimensional accuracy due to springback. Due to the lack of experience with these new materials, the conventional wisdom for formability and die development may fall short and sometimes will be erroneous.

Using CAE technology is a perfect solution for both challenges. Engineers can test out the

new materials in a virtual environment before committing to build the tool. For example, simulation allows CAE analysts to adjust boundary conditions (e.g., binder tonnage) to quickly identify the optimal value. It is much faster and more reliable than trial-and-error, especially for complex parts. The CAE technology also allows the investigation of several alternative forming options, such as tailor-welded blanks, sheet hydroforming, and superplastic forming, before making a feasible and cost-effective decision.

**Sheet Metal Forming Processes.** Sheet metal forming is one of the most important manufacturing processes in the automotive industry. Several different processes fall into this category. Among them, the conventional stamping process is the most widely used method because of its high speed and low cost. In this article, the term *sheet metal forming* implies primarily the stamping process and some variations listed as follows. The CAE technologies needed for simulating these forming processes are very similar:

- Conventional stamping
- Sheet hydroforming
- Tube hydroforming
- Superplastic forming

To limit the scope of this article, unusual forming processes, such as warm forming, electromagnetic forming, and explosive forming, are not covered.

One of the prerequisites for obtaining good results with CAE is to simulate the forming process as closely as possible to the physical process. The CAE by itself is not a magic tool. It will only give results of the process being modeled. The analysts must understand the details of the physical process and model it accordingly.

In a conventional stamping process, sheet metal parts are generally made in four stages, not including the blanking operation:

- Stage 10: (draw) forming
- Stage 20: trimming
- Stage 30: flanging
- Stage 40: final trimming and flanging

The stages are often called operation 10 through 40. The first die is the most important operation, in that it makes the majority of the final product shape. (Note: The term *die* usually implies the entire die, although sometimes this term refers to the female die, or die cavity). The first die has four pieces (punch, die, upper binder, and lower binder). This design allows die makers more flexibility to control the operation and to make good parts. However, it is rarely used at the present time due to the high cost. The other three stages often perform combined functions for complex parts. For example, the flanging die may perform a forming or restriking function in some areas while performing the flanging operation around the perimeter.

The majority of the deformation in the first die in a stamping operation is draw forming; hence, it is often called the draw die. Generally

speaking, there are two types of three-piece die: toggle draw (Fig. 2) and air draw (Fig. 3). The schematic drawings in the figures show the two different concepts. Each one has its advantages and disadvantages. The toggle draw requires a double-action press so that the punch and the binder can be controlled independently. In this process, the sheet metal blank rests on the binder portion of the lower die, which is stationary throughout the entire forming process. The upper ring moves down to force the blank to conform to the binder and hold the sheet metal in that position. The punch then follows to deform the sheet metal into the die cavity. The binder force may increase as the blank becomes thicker as it is being pushed into the cavity.

The air draw is the opposite of the toggle draw. The punch is stationary and sits at the bottom. The lower ring, supported by air pins or nitrogen

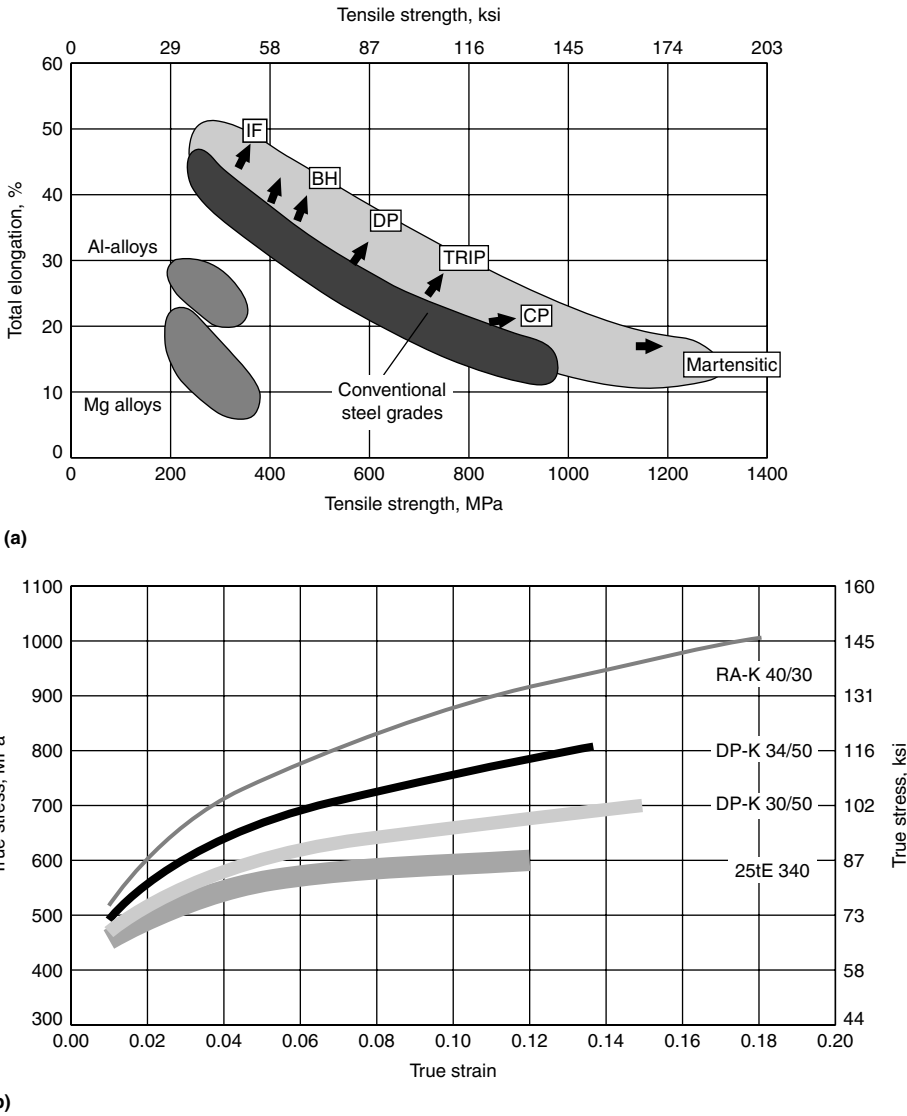

cylinders, is generally set above the punch so that the blank rests on the ring initially. The female die is on top of the blank and is attached to the ram. As the die moves down, it initially forces the blank to conform to the binder. The die continues to wrap the blank over the lower punch as the blank is being held by the upper and lower binder. The maximum binder force is dictated by the nitrogen cylinders. Insufficient binder force may force the binder open during the process.

### Formability and Sheet Metal Forming.

Before using any CAE methodology to simulate a process, one must understand the goal of the analysis. The goal for metal forming is to solve formability problems. Formability is defined as "the ability of the material (sheet metal) to be formed (under the specific process conditions) into the designed shape without failures." This simple statement covers five important issues. First of all, failure must be adequately and accurately defined. The other important concept is that formability is governed by four groups of factors:

- Product design (shape of the part)
- Blank used (the mechanical and physical properties of the blank)
- Die-face design (the addendum and binder)
- Forming process and operations

All four groups play an important role in affecting the formability in sheet metal forming (Table 1).

**Fig. 1** Trends in development of steel sheet properties. (a) Elongation and tensile strength of sheet steels. (b) Stress-strain curves for different cold-rolled steel grades (without predeformation, aged 170 °C, or 340 °F, for 20 min). IF, interstitial free; BH, bake hardened; DP, dual phase; TRIP, transformation-induced plasticity; CP, complex phase

**Fig. 2** Section view of a die in a double-action toggle press

**Fig. 3** Section view of a three-piece air-draw die

Although there are many factors, not all factors have the same impact on overall formability. Generally speaking, the following list gives the primary factors that a CAE model should focus on:

- Product design (shape of the part)
- Die-face development
- Blank shape and location
- Boundary conditions
- Material properties
- Process development

The most challenging and sometimes confusing part is that there is a strong interaction among these factors. The importance of each factor often changes, depending on other factors. For example, boundary conditions and blank shape/location may become more critical as the blank material is changed from steel to aluminum. A well-designed product and die-face development will be less sensitive to friction variations.

The formability concept discussed previously represents only a narrow view from the manufacturing perspective. A more complete definition of formability should be broadened so that “the formed part must meet all intended design functions and performance criteria.” It is essential to embed the product requirements in the formability guideline. If a product design is completely dominated by formability issues, many decisions made will lead to higher cost or

an inferior design not meeting performance criteria.

For example, aluminum-killed deep-drawing-quality mild steel (AKDDQ or DDS) offers excellent formability. It can be used to make complex or challenging parts. However, this grade of steel is soft and has relatively low yield strength. Structural parts made of this grade will have less desirable structural performance (including crash/safety) unless the gage of the steel is increased to compensate for the lack of strength. This countermeasure increases part weight and may not be an acceptable solution in today’s (2006) mass-conscious environment.

The narrow view of formability may also drive the design to be rounder (large radii), shallower, and more open angle (relative to the vertical wall). Those changes, while sometimes necessary, will compromise the structural performance. An optimal product development needs to carefully balance all requirements, including other manufacturing concerns, mass, and cost. The CAE offers opportunities to evaluate many of those issues before the die and other hardware are built.

Stamping simulation technology has matured over the past decade. Finer and more detailed models have drastically improved the forming analysis capability from investigation level to tuning and validation, with proven productivity gain and cost-efficient solution. However, during recent years, new requirements have surged, such as quality, springback, and tolerance control, as well as integration of the manufacturing effects (including assembly) on product performance analysis, such as fatigue, crash-worthiness, and so on. These requirements have become even more persistent with the introduction of new material grades such as aluminum alloys, ultrahigh-strength steels, dual-phase steels, and so on in order to control energy consumption in the transport industry in particular.

Current available stamping simulation software, which was designed more than 10 years ago to support formability issues, has started to reach its limits. Consequently, new-generation software has become a necessity to handle new industrial requirements. In-depth solver review, including element formulation, contact algorithm, parametric material modeling, and so on, was fundamental in ensuring the accuracy improvement of the forming results regarding stress and strain within the required tolerance. Moreover, the strong time-to-market pressure left a very narrow time window to perform forming simulations in order to impact the design decision. Therefore, the overall simulation process has been upgraded and streamlined. Quicker die run-off design and a quicker incremental solver fill the gap between die design and simulation. The objective is to create the first draft of a die addendum in just a few minutes. This allows earlier simulation involvement, process optimization, and eliminates costly downstream problems. Furthermore, massive parallel processing (MPP) represents the optimal solution

for the speedup of the validation phase with the hardware evolution. The industrial MPP version needs new innovative solver architecture. This new architecture also allows strong interaction with the customized user interface. Advanced object concept and new data model assess sophisticated simulation data management and transfer for active process/performance coupling analysis, in a collaborative and concurrent engineering environment.

#### Evolution of Computer-Aided Engineering for Sheet Metal Forming—History Overview.

The use of the finite element method (FEM) for sheet metal forming applications created strong interest for researchers and industry users in the fourth quarter of the 20th century. Throughout the 1970s and early 1980s, most studies were limited to either axisymmetric or plane-strain problems or to three-dimensional (3D) problems with simple geometry, such as cups. However, these studies only provided general information on a variety of important issues on sheet metal forming and were of little use for the complicated 3D sheet metal forming problems. Except for can making, the technology did not offer practical industry applications.

The technology continued to grow in the ensuing 10 years, with an emphasis on real applications in the automotive industry. People began identifying and studying various issues related to CAE methodology for sheet metal forming. Better material models, such as Barlat’s 1989 and Hill’s 1990 yield loci, were published (Ref 1, 2). More practical contact treatment was developed. Some automotive applications, such as roofs, fenders, and hoods, were studied. At this stage, different attempts were also made with non-FEM-based approaches, such as expert system and knowledge-based methods.

In the 1990s, more vigorous research and development was being carried out to improve the reliability and accuracy of sheet metal forming simulation. Many valuable papers were published in the NUMISHEET and NUMIFORM series of international conferences (see the Selected References), although a good number of papers also appeared in various conferences (such as the SAE Congress) and publications. NUMISHEET has become the most recognized conference for sheet metal forming simulation. It is exclusively dedicated to sheet metal forming (including hydroforming) simulations and has been organized by volunteers without the support of any permanent organization since the first conference was held in 1991 in Zurich. The conference traditionally covers the following subjects:

- Theoretical development in all aspects
- Experimental works
- Industrial applications
- Benchmarks

Since 1993, the technology has made significant and rapid progress in many different areas. Considerable efforts were made in improving the challenges for dealing with complex industrial parts so that more process details and bigger

**Table 1 Variables that affect formability**

Variable	Property affected
Product	Shape (depth, radii, angle) Flange
Blank physical characteristics	Shape Location Thickness Edge condition Tailor-welded blank weld line
Blank material mechanical properties	All properties related to the constitutive model/equation
Die	Face design (tip, addendum, binder) Surface finish and coating Material Surface hardness Rigidity Guidance Alignment Temperature
Die lubrication	Friction Lubricant type Film thickness Wetness (distribution)
Process	Forming type (stamping, hydroforming, etc.) Forming process (trimming, flanging, etc.) Ram guidance and speed Counterbalance/rigidity of the press Shim blocks Ambient temperature and humidity Prebending
Process control	Binder pressure/force Pad pressure/force Draw bead

model sizes can be analyzed. Several critical technology breakthroughs occurred in the mid-1990s. Most notable were the successful development of automatic meshing for dies and the adaptivity for the deformable sheet metal. The main emphasis during that period was focused on formability evaluation from blanking through trimming operations. Users were looking for answers to straining, thinning, wrinkling, and failure predictions.

There were two major breakthroughs in the next period, beginning in 1999. One was the improvement of springback prediction, as a result of several global multiyear consortia. The most important of these was the Springback Predictability Project, funded by the National Institute of Standards and Technology Advanced Technology Program (NIST-ATP). Due to the work of this consortium, the industry finally had a code that could provide decent springback prediction for some parts. Another major development was the emphasis of a user-friendly metal-forming system that integrated all needed functions, including some computer-aided design (CAD) work that used to be done outside of the system.

The rapid developments of software technology, together with faster and lower-cost computer hardware, have enabled many metal-forming operations to be modeled cost-effectively. Simulation lead time has been decreasing significantly since 1990. Figure 4 shows that the simulation lead time for total analysis (including meshing, setup, calculation, and visualizing the results) of one panel (based on a front fender from Mazda) was reduced from 50 days in 1990 to approximately 10 days in 2002.

Fig. 4 Reduction in lead time for simulating the stamping of an automotive panel

The total turnaround time for all tasks, including die-face generation, formability analysis, and springback prediction, has been reduced to less than one week since 2004. These data are very representative throughout the global industry. This dramatic reduction in total simulation time was also influenced by standardized setup and more experienced CAE analysts to produce a rapid and qualitative forming evaluation.

Proper use of forming simulations can effectively reduce physical testing and costly downstream problems by solving the problems upfront in the early development stage. Over the years, successful stamping simulation has helped to considerably reduce the costs and lead time for the automotive industry, partially due to the technology growth. The industry applications of sheet metal forming simulation have grown enormously in recent years as the benefits of troubleshooting dies on the computer, rather than through extensive shop trials, have been realized.

There are countless examples of these savings. For example, Hyundai was able to cut total turnaround time by half, while improving the quality in the development of a full-body side panel with the use of stamping simulation. This led to a large increase in the need for CAE analysts for this field, and a huge increase in further research and development work supporting the technology.

Over the last decade, more drastic lead time and cost reduction have come from overall process optimization with the introduction of concurrent engineering, parallel tasking, and the optimization of different tasks using the CAE technology. Further speedup in this area is expected with the emergence of new computer technologies and the industrialization of MPP technology using modern configuration such as clusters and so on.

## Methodology

The term *computer-aided engineering* simply means performing engineering analysis as the product is being designed and developed. It does not imply finite element analysis (FEA) using FEM. However, many people use all three terms interchangeably, mainly because FEM has become more powerful and accurate in the last 10 years. Supporting technology such as automatic mesh generation has also improved significantly. Hence, other simpler forms of analysis have become nearly obsolete.

For the completeness of this article, many forms of CAE methodology are discussed.

Fig. 5 Schematic view of a section

However, the emphasis is given to software tools using 3D FEM technology.

**Simplistic Approaches.** There are many different approaches to analyzing formability. Length-of-line analysis is at one end of the spectrum, and 3D FEA is at the other. The length-of-line analysis is unbelievably crude in today's (2006) standard. However, it was used well into the 1990s, before any CAE methodology became truly useful. The method simply calculates the ratio between the final length of a cut section and its original length (Fig. 5).

Before 3D FEM became practical, some 2D analysis techniques were explored. The earlier approach used either bar or beam elements to model a section line of a forming die. One good example of such a code is LINEFORM, developed at General Motors. These 2D solutions could take care of the challenging sliding contact problems in an ideal condition. A more advanced approach was to use shell elements with additional boundary conditions to force a 3D model to behave like a 2D problem. The first approach is much faster but has very limited applications. The second approach offers more realistic contact, especially for a more complex section line. However, it is also much slower compared to the previous method.

There were two major reasons to use the 2D approach. First, 3D FEM was not very practical until the mid-1990s. The 2D approach was much faster and more stable. Secondly, developing the die face on the computer was a very slow process in those days. The 2D solution provided some guidelines to the initial die-face design. Although the technology was relatively crude compared to a 3D analysis, it was better than experience-based die-design methodology. With the advancement of CAD and CAE technology, the need for 2D FEM simulation has diminished tremendously.

**3D FEM Approaches.** The earliest form of FEM was first introduced in the 1940s. The initial general application was for structural stiffness analysis in the 1960s. However, simulation of general sheet metal forming problems came much later. The work done by Wang and Budiansky was probably one of the earliest successful cases to model it in 3D formulations (Ref 3).

There are many technical reasons that 3D FEM simulation for metal forming did not become practical for production use compared to other application areas. In order to obtain reasonably reliable results for real production parts, the following formulation issues for FEM technology needed to be resolved:

- Large displacement
- Large deformation
- Large rotation
- Large sliding with nonlinear contact
- Efficient and reliable contact treatment
- Element formulation to handle through-thickness variation in order to model combined stretching and multibending and unbending

- Advanced material model to handle anisotropy and cyclic loading
- Advanced friction model to capture the surface traction
- Intelligent adaptivity algorithm to refine the mesh as needed

A significant advancement in this area began in the early 1990s. The majority of the issues listed have been overcome with new technology that was developed and enhanced between 1990 and 2000. Although most of the early work was done by academia, codes developed by some commercial software companies have been the primary workhorses in real-world applications. The current market is primarily dominated by AutoForm of AutoForm Engineering, LS-DYNA of Livermore Software Technology Corporation, and PAM-STAMP of ESI Group. They successfully built their own codes based on early codes from academia. Over the years, they continuously enhanced their codes with in-house development or implementation of published work. Few people in the industry use codes other than these three codes.

One of the most important technologies in a 3D FEM code is the time-integration scheme. Generally speaking, this can be divided into two major families: explicit time integration and implicit time integration. Both algorithms can be applied to either static or dynamic governing equations. Hence, there are four possible fundamental formulations used by the FEM codes:

- Static Implicit (SI)
- Static Explicit (SE)
- Dynamic Implicit (DI)
- Dynamic Explicit (DE)

Among them, the static implicit formulation is widely used for static or quasi-static problems such as structural analyses. The dynamic explicit formulation is widely used for dynamic problems such as drop tests and vehicle crash simulations. However, the choice of integration algorithm for metal-forming applications was not that obvious in the early years as FEM started to be used in this field. The majority of researchers thought static implicit formulation was more rigorous and suitable for accurate results for metal-forming simulations.

By 1990, almost all successful sheet metal forming simulations published in major conferences and technical journals used the static implicit approach, with a few exceptions using the static explicit formulation. As papers using dynamic explicit formulations began to increase

throughout the 1990s, the debate about this issue continued for many years. One major reason fueling the debate was that the majority, if not all, of the codes used a single time integration method. Most debates seemed to focus on justifying the superiority of their own codes rather than a fair comparison of the advantages and disadvantages of each method. Table 2 gives some well-known codes representing each method.

Note that the codes listed in Table 2 were those popular during that period. Some of them may not be available today. SHEET-x represents several codes from The Ohio State University. The dynamic implicit method was available as an option in some dynamic-explicit-based codes.

Many comparison works were published by static implicit proponents using unreasonable parameters to illustrate why dynamic explicit was not appropriate for metal-forming simulations. Those conclusions were obviously very misleading. There is no single ideal method that can be used for all types of forming problems or all stages of the forming process. The choice of method hinges on a good balance of many critical issues, depending on the specific application being simulated.

The static implicit formulation used for metal-forming simulation is very similar to the one used for structural analysis. It transforms all externally applied force (such as the moving punch) into internal energy, due to the deformation of the sheet metal. The equilibrium state is maintained at every state. This method has been demonstrated to be far superior to other methods simulating small-scale lab-type parts such as cups. The drawbacks of the static implicit method are its storage and central processing unit (CPU) requirements that grow nearly as a cubic function of the number of elements. As the size or the complexity of the geometry grows, the static implicit approach becomes less practical. As computer random access memory price decreases and CPU speed increases as Moore's law predicts, this may become more possible but still less efficient compared to dynamic explicit codes.

There are other issues that limit the widespread use of static implicit codes in a production environment. Sheet metal forming is not really a "pseudostatic" problem. In a typical stamping operation, the actual forming completes the total travel of 100 to 150 mm (4 to 6 in.) in 2 to 3 s, with the peak speed close to 500 mm/s, (20 in/s). The sheet metal flows in various

directions and changes in the process of forming. Most areas (nodes in FEA) of the sheet metal have large displacement and large rotation in addition to large deformation (in elements). This limits the step size of static implicit codes in order to capture the physical behavior of the metal.

The other challenge is that the contact between the metal and the dies is highly nonlinear. Correctly capturing the contact and calculating the friction force is not an easy task for static implicit codes. Capturing the onset of wrinkling and correctly predicting the actual formation of wrinkles are also difficult challenges for static implicit codes. One fundamental characteristic of the static implicit algorithm is the need to invert the stiffness matrix. As the complexity and the size of the problem grow, convergence slows down tremendously or cannot be accomplished at all.

The basic governing equation of dynamic explicit codes has an inertia term similar to the following equation. Different codes may use different formulations, but the concept of the momentum equation is the same:

$$f^{\text{int}}(u) + c\dot{u} + m\ddot{u} = f^{\text{ext}} \quad (\text{Eq. 1})$$

where  $f^{\text{int}}$  is the internal force,  $f^{\text{ext}}$  is the external force,  $c$  is damping,  $m$  is mass,  $u$  is displacement,  $\dot{u}$  is velocity, and  $\ddot{u}$  is acceleration.

Critics of dynamic explicit codes argue that equilibrium is never maintained. This statement is a little misleading. In dynamic explicit codes, equilibrium is dynamically balanced. It is true that the inertia force may be exaggerated, mostly due to user error. In that case, the quality of the solution will deteriorate. If a user chooses a proper setting so that the inertia is no more than 5%, the solution quality should be good.

Static explicit codes were presented as taking the advantages of both static implicit and dynamic explicit codes. It was actively promoted in the 1990s. The results seem to indicate that static explicit codes have the weaknesses of both codes. The popularity of this group greatly diminished in the late 1990s after the third NUMISHEET conference in 1996.

AutoForm, from AutoForm Engineering, is a unique code. Some people classify it as a *fast implicit* code. It uses the same governing equation as the static implicit codes. The major reasons for its fast performance are that it uses membrane element and some decoupled proprietary techniques. Among them, the matrix is decoupled and simplified. This allows the matrix to remain small with a high convergence rate. Although many experts doubt the technical soundness of some of the techniques used by AutoForm, the code seems to generate relatively good results in most cases.

**Adaptivity.** Proper mesh definition is always important for all FEM simulation. However, it is not practical to use fine mesh for the entire blank from the beginning of a forming operation due to the high CPU hours needed. Adaptivity can intelligently refine the blank mesh only in the

**Table 2 Summary of metal stamping codes by integration algorithm**

Method	Code names
Static implicit	ABAQUS (standard), ADINA, MARC, INDEED, NIKE, Metalform
Dynamic explicit	LS-DYNA, PAM-STAMP, OPTRIS, RADIOSS, LLNL-DYNA, ABAQUS/Explicit, DYTRAN, DYNAMIC
Static explicit	ITAS, ROBUST, SHEET-x, Panelform

Note: ABAQUS, ABAQUS, Inc.; ADINA, ADINA R&D, Inc.; NIKE, Lawrence Livermore National Laboratory; LS-DYNA, Livermore Software Technology Corp.; PAM-STAMP, ESI Group; OPTRIS, Dynamic Software; RADIOSS, Mecalog Group; LLNL-DYNA, Lawrence Livermore National Laboratory; DYTRAN, MSC Software; SHEET-x, The Ohio State University

areas needed. Users do not have to figure out a “smart” mesh pattern to capture the deformation gradient correctly. It is especially essential for the deep drawing operation, when the sheet metal often has large displacement. Adaptivity has been around for many years but was not popular until 1995, due to some limitations of earlier adaptive algorithms.

Since 1997, it has become standard practice among the majority of CAE analysts to use adaptivity regardless of the software used, because the technology provides fast and reliable results. By the late 1990s, all metal-forming software also developed intelligent algorithms that can foresee contact problems and refine the mesh before it is needed. Although the details of the algorithms may be different, they are all based on the element normal differences between adjacent elements in the approaching tooling mesh.

The algorithms work well in most stamping cases. However, a different criterion may be needed in some special cases. It does not work at all in other types of simulation, such as crashworthiness. It is desirable to modify the algorithm to use a different index other than angle differences. Those indexes may include thinning, effective stress, or effective strain.

The purpose of adaptivity is to refine the mesh. There are three fundamentally different approaches:  $h$ -adaptivity,  $p$ -adaptivity, and  $r$ -adaptivity. The most common method used by sheet metal forming software is  $h$ -adaptivity. This method splits the elements when the criterion is met; hence, it is dubbed as “fission.” Although there are some variations in  $h$ -adaptivity, often each element is split into

four elements. Adaptive constraints are applied to middle nodes to take care of connectivity requirements. This method is relatively easier to implement, especially for a complex code so as to avoid incompatibility issues. Figure 6 is an example of a uniform blank mesh and a refined mesh at the end of forming, with four levels of refinement.

It is potentially possible to merge previously split elements into a bigger element when desired. This is often dubbed as “fusion.” The main purpose of fusion is to speed up the calculation and reduce the memory required. However, fusion provides some but not significant speed-up benefit for dynamic explicit codes. On-the-fly fusion, shown in Fig. 7, often causes more perturbation and creates more stress noise in dynamic explicit codes. Hence, it may not be a preferred practice. However, it can be applied between operations to save time for the subsequent calculation. This is also called coarsening by some codes.

**Material** model is very important to get good results in a metal-forming simulation. There are many available material yield criteria to describe different material properties. One of the most popular models used in the early years of stamping simulation was a planar-isotropic, which was based on Hill’s material model published in 1948 (Ref 4). This yield criterion is an improvement over the von Mises yield criterion by accounting for normal anisotropy. This planar-isotropic yield criterion for plane stress is:

$$\bar{\sigma}^2 = \sigma_{11}^2 - \frac{2R}{(R+1)}\sigma_{11}\sigma_{22} + \sigma_{22}^2 + \frac{2(2R+1)}{(R+1)}\sigma_{12}^2 \quad (\text{Eq 2})$$

where  $\sigma$  is stress, and  $R$  is the anisotropy parameter.

Considering only the principal stresses, this equation can be simplified as:

$$\bar{\sigma}^2 = \sigma_1^2 + \sigma_2^2 + R(\sigma_1 - \sigma_2)^2 \quad (\text{Eq 3})$$

This yield surface is an improvement over the Tresca yield surface (an irregular hexagon) and the von Mises yield surface (an ellipse). However, it seems to exaggerate the influence of the anisotropy, especially in the biaxial stretching quadrant. Hosford proposed a yield criterion in

1979 that is mathematically similar but with a high-order exponent (Ref 5):

$$\bar{\sigma}^m = \sigma_1^m + \sigma_2^m + R(\sigma_1 - \sigma_2)^m \quad (\text{Eq 4})$$

where  $m$  is a mathematical exponent.

Exponents of  $m = 6$  and  $m = 8$  were proposed for body-centered cubic materials such as ferritic steel and face-centered cubic metals such as aluminum, respectively. This locus lies between the Tresca criterion and Hill’s quadratic form and matches experiments better, compared to the other three criteria. However, this minimizes the influence of anisotropy due to its high exponent, and it does not address the planar anisotropy issue. Deep-drawn cups such as beverage cans made of certain metals have a strong earing phenomenon. This is due to the directional anisotropy in the plane of certain metals, such as the extradeep-draw-quality steel. The following equation is a general form of the aforementioned yield function that considers the anisotropy in both the rolling and transverse directions:

$$2\bar{\sigma}^m = \frac{2}{(1+r_0)}[\sigma_1^m + (r_0/r_{90})\sigma_2^m + r_0(\sigma_1 - \sigma_2)^m] \quad (\text{Eq 5})$$

where  $r$  is the anisotropy parameter.

When  $m = 2$ , Eq 5 is the same as the von Mises yield criterion if  $r_0 = r_{90} = 1$ , and it represents Hill’s 1948 quadratic yield criterion if  $r_0 = r_{90} = R$ . It coincides with Hosford’s 1979 yield criterion given in Eq 4 when  $r_0 = r_{90} = R$ .

While the thinning calculation in dynamic explicit codes is less dependent on the stress and material model, it is crucial to have a good material model and stress calculation for springback analysis. As the use of aluminum and advanced high-strength steel increases, springback becomes a pronounced concern. Accordingly, the accuracy of springback prediction is vital before it can be minimized. The first step in solving the problems mathematically is to obtain accurate stress distribution. To this end, the choice of the right material model and the yield criterion is very important.

Barlat and Lian proposed a model in 1989 that was developed with aluminum alloys in mind (Ref 1). This model offers improved agreement

(a)

(b)

**Fig. 6** Example of (a) uniform mesh of blank and (b) refined meshes after forming

(a)

(b)

**Fig. 7** Example of a mesh pattern difference between (a) regular adaptivity and (b) adaptivity with fusion

compared to models with Hill's 1948 model with planar isotropy. It is less complex compared to Barlat's later models; hence, it is easier for implementation:

$$2\bar{\sigma}^m = a\{|K_1 + K_2|^m + |K_1 - K_2|^m\} + c \cdot |2K_2|^m \quad (\text{Eq 6})$$

where  $K_1$ ,  $K_2$ ,  $a$ ,  $c$ , and  $h$  are defined as:

$$\begin{aligned} K_1 &= \frac{1}{2}(\sigma_1 + h\sigma_2) \\ K_2 &= \sqrt{\left(\frac{\sigma_1 - h\sigma_2}{2}\right)^2 + p^2\sigma_{12}^2} \\ a &= 2\left(1 - \sqrt{\frac{r_0}{1+r_0} \frac{r_{90}}{1+r_{90}}}\right) \\ c &= 2\sqrt{\frac{r_0}{1+r_0} \frac{r_{90}}{1+r_{90}}} \\ h &= \sqrt{\frac{r_0}{1+r_0} \frac{1+r_{90}}{r_{90}}} \end{aligned} \quad (\text{Eq 7})$$

The variable  $p$  does not have a close form solution, and it is found by an iterative search to solve the  $g(p)$ :

$$g(p) = [2m\bar{\sigma}^m / (\partial\Phi/\partial\sigma_1 + \partial\Phi/\partial\sigma_2) \cdot \sigma_{45}] - 1 - r_{45} \quad (\text{Eq 8})$$

The Corus-Vegter model is a refined case of the original Vegter model, and it is essentially a discrete yield description, derived from several experimental measurements. This yield model has the potential to be more accurate in representing the yield surface and effective in improving the results of simulations, in both formability and springback predictions.

The Corus-Vegter model may have some advantages over the commonly used yield models today (2006). A comparison between Hill 1948, Hill 1990, and Vegter yield loci is shown in Fig. 8. The Vegter model is constructed through four points on a quarter of the yield ellipse; both the point and the slope (or tangent) are either measured or are known. Bezier interpolation between the points and two symmetry planes are then used to construct the planar ellipse. Cosine interpolation between the 0, 45, and 90° measurement sets is used to construct the entire yield surface description.

The general consensus is that isotropic hardening does not accurately describe the sheet metal behavior and always notably underpredicts springback. This helped encourage a substantial amount of work on the kinematic hardening model. However, the results do not support the theory that kinematic hardening models are generally superior to isotropic hardening models. Springback calculations using a kinematic hardening model often (but not always) overpredict the springback amounts. The Chaboche model was implemented by some metal-forming codes. However, the results in

terms of springback prediction are inconclusive for various reasons. A combination of isotropic and kinematic hardening models that account for anisotropic behavior may be a potential material model to use.

There are several important criteria for choosing a proper model. First, the parameters needed for the model can be easily acquired through relatively simple tests. Second, the model should not create too great a cost penalty in using it. Third, it should not cause too many numerical complications that compromise the accuracy due to approximation or round-off error. Fourth, it should not involve parameters that require adjustment from case to case.

Many more advanced models and yield criteria have been proposed since 1989. However, these advanced material models, although theoretically sound, often do not give better springback prediction. The confusing results may be due, in part, to the stress noise commonly seen in analyses with dynamic explicit codes. The stress noise is the result of stress wave propagation and penalty-method-based contact algorithm. More studies are needed to better understand the root cause.

## Failure Criteria for Sheet Metal Forming

In FEM simulation, the sheet metal does not necessarily fail unless a proper failure criterion is used. Besides, the code cannot always simulate the failure precisely at the right location and at the right time. The use of different material criteria and numerical noise may have an effect on the initialization of necking, and it is necessary for the user to specify a failure criterion in order to be more accurate in evaluating sheet metal formability. Most users determine failure by postprocessing the results, which can be done by comparing thickness distribution, for example, against a predetermined value. Any areas with values above the limit are considered failures. This approach is simple and efficient. However, it may not accurately show

Fig. 8 Comparison of Hill 1948, Hill 1990, and Vegter yield ellipses in the 45° direction

the problem for several reasons. The limiting thickness is not a constant value but a strain-path-dependent value. To better predict the failure of sheet metal, several failure criteria have been used, as discussed subsequently.

**Experimentally Based Forming-Limit Curves and Forming-Limit Diagrams.** Before CAE technology became mature enough for use in metal-forming analysis, empirical methods were used to provide the relationship between acceptable formability and strain state. Perhaps the best known of these is circle grid analysis (CGA). The CGA technique was used with controlled tests forming domes, cylindrical cups, and so on and special tensile tests to determine limiting strain states. First, grid patterns of circles are imprinted or etched on the surface of a sheet metal blank. The marked blank is then formed into a part. During forming, as the sheet metal is deformed to the final shape, the circles are deformed into ellipses (Fig. 9). The change of shape then gives the state of strain at each point, as shown in the diagram in Fig. 9. The data can be used to construct a forming-limit curve (FLC).

Although it was initially developed to be used in the field, CGA concepts still provide a useful way to visualize and comprehend the changes that occur during the forming process. The strain induced from the deformation, whether from measurement or from analysis, can be plotted on a forming-limit diagram (FLD). The FLD is a diagram with all of the strain data, compared against the FLC that is based on the material being used.

The FLC developed by Dr. Stuart Keeler is the most popularly used failure criterion for sheet metal stamping, and sometimes for hydroforming. The concept and data were first published by Dr. Keeler in the 1960s (Ref 6, 7). Dr. Keeler later refined his original publication with more details based on his work at National Steel and at Budd Company. However, the later information

Fig. 9 Deformation of an imaginary circle on the blank

was released with reference to the earlier publications without complete details. Some information was given in graphic form without equations. Hence, it is necessary to summarize this standard FLC in equation form for anyone who is interested in doing his/her own calculation or implementing it in computer codes.

The fundamental methodology (data and guidelines) that Keeler developed was for low-carbon steel (including mild steel and high-strength low-alloy steel). It can be summarized as follows:

- In sheet metal forming, any deformation can be described using the primary principal surface strain (major) and secondary principal surface strain (minor).
- The shape of the FLC remains constant.
- The FLC moves vertically on a major-minor strain chart based on the position of the  $FLD_0$  that is influenced *only* by the  $n$ -value and the thickness of the steel.
- The marginal curve is generated by subtracting 10% (engineering strain) from the FLC (e.g., 25% for  $FLD_0$  of 35%).

The previous statements are not perfectly accurate but are good enough for practical use. This simplified version makes implementation of CGA and FLD on the shop floor much easier. The equations and the guidelines can be used on low-carbon steel only. No comprehensive study for other types of materials is available.

**Empirical  $FLD_0$ .** The  $FLD_0$ , in percent engineering strain, is defined as:

$$FLD_0 = N \cdot T \quad (\text{Eq 9})$$

with:

$$N = \min(n/0.2116, 1.0)$$

$$T = 23.26 + 14.02 \cdot \min(t, 3.0)$$

where  $N$  represents the material effect due to work hardening ( $n$ -value), and  $T$  represents the

thickness effect based on the initial thickness of the sheet metal in millimeters. There are some minor variations of the formula and parameters throughout the industry, but the difference is so minute that it is not of concern. The stamping community slightly modified Dr. Keeler's theory in the late 1980s (according to his advice). The revised guidelines set no limitation on the  $n$ -value effect and reduced the thickness effect as follows:

$$\text{Let } N = n/0.2116 \quad (\text{Eq 10})$$

Then:

$$\text{For } t < 2.5 \text{ mm} \quad T = 23.26 + 14.02 \cdot t \quad (\text{Eq 11})$$

$$\text{For } 2.5 \text{ mm} < t < 5 \text{ mm} \quad T = 20.0 + 20.2 \cdot t - 1.95 \cdot t^2 \quad (\text{Reduced thickness effect})$$

$$\text{For } t > 5 \text{ mm} \quad T = 72.25 \quad (\text{No more thickness effect})$$

The new equations affect only heavy-gage steel (thickness greater than 2.5 mm, or 0.10 in.). The results of the two sets of equations are shown in Fig. 10. The revised equations better describe the low-carbon steel characteristics and should be used. However, many people are still using the original equations for various reasons.

**Empirical FLC.** The shape of the FLC for low-carbon steel can be described with the following equations:

$$e_{\text{maj}} = FLD_0 + e_{\text{min}}(0.027254e_{\text{min}} - 1.1965) \quad (\text{Eq 12})$$

$$e_{\text{maj}} = FLD_0 + e_{\text{min}}(-0.008565e_{\text{min}} + 0.784854) \quad (\text{Eq 13})$$

Equation 12 is for the left side ( $e_{\text{min}} < 0$ ) of the curve, and Eq 13 is for the right side ( $e_{\text{min}} > 0$ ). All of the strains in the preceding equations are percent engineering strain. In other words, the value of 5% engineering strain in the equation is

5. For a material with the  $n$ -value equal to 0.212 and 0.75 mm (0.03 in.) thickness ( $t$ ), the  $FLD_0$  is 33.78% (engineering strain). This standard Keeler FLD in engineering strain is shown in Fig. 11.

For FEM codes using true strain, all strain data must be converted using the engineering strain value (i.e., 0.05, not 5 for 5% strain) to the true strain value. In the true strain domain, the left side of the FLC is a 45° straight line (Fig. 12). Hence, only one data point is needed on the far left in a true strain domain using the following equation:

$$e_{\text{maj}} = FLD_0 - e_{\text{min}} \quad (\text{Eq 14})$$

Fig. 11 Standard Keeler forming-limit curve (FLC) ( $n = 0.21$ ;  $t = 0.75$  mm, or 0.03 in.)

Fig. 10 Difference between the original and revised formula for the thickness effect

Fig. 12 Forming-limit curve (FLC) in true strain ( $n = 0.21$ ;  $t = 0.75$  mm, or 0.03 in.)

All numbers in this equation are true strain. For example, 35% engineering strain becomes 0.30 ( $= \ln [1 + 0.35]$ ) in true strain, not 35 or 0.35. Figure 12 shows an FLD in true strain units.

Although Keeler's standard FLD is quite simple, it may still be used incorrectly due to misunderstandings. The most common mistake is using the percent engineering strain value on an FLD in true strain units. Then, the mistake could be as big as 50% (engineering strain). The preceding equations have been adopted and used by several commercial codes.

Generally speaking, most European interpretations of the FLD<sub>0</sub> have little or no thickness effect. The marginal curve is generated differently in many other countries (especially in Europe). Instead of shifting the FLC down by a fixed amount, (the major strain value of) the marginal curve is a percentage (e.g., 80% or 0.80) of (the major strain value of) the FLC, hence creating a variable bandwidth for the marginal zone.

**Thickness-Based Forming Limit.** Some analysts prefer the thickness-based forming limit for various reasons. First, it is easy to use and easy to compare against the measurement. Second, the Keeler FLC previously described was based on a nearly linear strain path, without significant bending and unbending deformation. It becomes very questionable to use the same failure criterion for multistage forming analysis. Thickness limit is an option to address this issue. One popular method is to simply convert the FLD<sub>0</sub> to limiting thickness based on constancy of volume. Some engineers choose to use a safety factor in conjunction with the limiting thickness reduction. Some simply choose a conservative number, such as 20%, as the failure criterion. Although these methods work fine, more study is needed to offer a more definitive criterion.

**Theoretical Forming Limit.** Due to the limitation of Keeler's FLC, numerous researchers have been working on theoretical forming-limit prediction for many years. That work is very useful because metal normally does not follow a simple linear strain path in a typical forming operation. It is more crucial to have a reliable way to predict failure in a multistage forming operation. Most theoretical forming-limit prediction assumes that the failure is caused by localized necking on the left side of the FLD and diffuse necking on the right. The classical theory used simple power law for the constitutive equation and isotropic hardening. The prediction was much lower than experimental results.

The most common method used for predicting localized necking for the right side of the FLD is the Marciniak-Kuczynski (M-K) method (Ref 8, 9). It is often used to generate FLCs for various reasons, especially in the absence of reliable or sufficient experimental data. The M-K method requires a pre-existing defect in the material. This defect can be caused by any combination of geometric and material nonuniformity. The most common approach is to characterize the defect

by a reduction in the material thickness. The thinner material will actually experience higher strain than the neighboring material and eventually reaches the forming limit.

The M-K method is a strain-based approach that is easy to understand and seems to be a sound approach; however, comparisons between the predictions and the experimental data are inconsistent. It is influenced by the material model used and generally predicts a very high forming limit unless a large pre-existing defect value is used. Many technical papers based on the M-K model have been published to improve the correlation between the prediction and measurements for various materials.

Another approach toward predictive FLDs is to apply a damage mechanics model to predict the failure controlled by fracture. This method takes into account the effects of initiation, growth, and coalescence of the microdefects in "real-life" material up to its final rupture. It can predict diffuse necking, localized necking, and rupture of metal sheets under both proportional and nonproportional loading conditions. The advantage of this approach, according to Ref 10 and 11, is its potential broader application to cover deformation of any strain path. The results seem to be better than the conventional methods in predicting the formability of the sheets under biaxial stretching. The theoretical failure model can be incorporated into stamping finite element codes for more realistic prediction, and its results can be incorporated into other applications such as crash simulations to improve the correlation. However, this model has not been adopted widely, possibly due to its intense calculation.

Strain path effects on conventional strain-based FLDs have been published by many researchers working on theoretical FLC prediction. It has also been reported by many experimental works. Figure 13, from the work done by Graf and Hosford on 2008-T4 aluminum (Ref 12, 13), is an excellent example of the path dependency of the forming limit. First, legs of the dashed lines represent the prestrain state for each test condition. The heavy black line is the FLC for the as-received material. Each additional FLC represents the new forming limit following the indicated prestrain.

The huge variation of the FLC in a two-stage deformation makes one wonder whether the material truly has significant forming limit. Experimental evidence for a path-independent stress-based FLD has been reported in the literature, suggesting that the path dependency of the strain-based approach arises from the path-dependent constitutive laws governing the relationship between the stress and strain tensors. The stress-based FLD can now be used equally well for all forming processes, without concern for path effects.

In 1977, Kleemola and Pelkkikangas first proposed using a stress-based FLD as an alternative for FLC prediction (Ref 15). They gave some experimental results that supported the path independence of the forming limit in stress

space for these materials. Arrieux et al. (Ref 16) reaffirmed this phenomenon and proposed using a stress-based criterion for all secondary forming operations. Despite these earlier works, the significance of a path-independent stress-based FLD went largely unnoticed until 2000. Stoughton (Ref 17) rediscovered the effect and proposed that it is necessary to use the stress-based criterion in all forming operations, including the first draw die, in order to get a robust measure of forming severity.

Stress-based FLCs are very useful, not only for multistage deformation. Many areas in a panel with complex product shapes, especially around the depressions with re-entrant surfaces, often go through strain-path changes in the first forming operation. A simple and consistent forming-limit algorithm that can be used throughout the entire forming operation without prior knowledge of the strain path is very beneficial and accurate in predicting the failure of the material.

The use of stress-based FLDs still faces several challenges before it can be fully accepted in production use. First, in any FEA calculation (especially with dynamic explicit codes), noise in stress calculation is unavoidable. If those stress states are put into FLDs for evaluation, stress point will change dramatically from one step to the next. As a result, it will generate obvious error in failure evaluations. Secondly, unloading is another issue that needs to be addressed in stress-based FLDs. When the material encounters unloading in the subsequent forming operation after exceeding the limiting stress, this location will appear safe on the FLDs. Thirdly, it is difficult to evaluate safety margin. From Fig. 13, it is seen that after initial yielding, the band between the limit stress and the initial yield stress is very narrow. Hence, it will be very difficult to estimate the remaining formability.

## Numerical Procedure for Sheet Metal Forming

The most important concept in sheet metal forming CAE is simulation. To obtain

Fig. 13 Prestrain path dependency for the forming limit of 2008-T4 aluminum. Source: Ref 14

meaningful results, the analysis must be set up to emulate the physical process as closely as possible; otherwise, the results may not be meaningful. For example, gravity may not be important in the draw-forming operation. It could make a difference in blank setting and binder wrap.

A typical complete stamping operation for the entire line of dies has five stages:

- Blanking
- Forming
- Trimming
- Flanging
- Trimming, flanging, and restriking

However, a complete stamping simulation will require more steps:

1. Blanking
2. Gravity loading
3. Binder closure
4. Forming
5. Springback
6. Trimming
7. Springback
8. Flanging
9. Springback
10. Trimming, flanging, and restriking
11. Springback

Although some software allows the user to set up the entire operation in one job setup, those functions still need to be activated sequentially. It is not common to do the entire line die analysis for various reasons. These include lack of manpower, insufficient computer capacity, lack of knowledge, and limitation of the software. On the other hand, it is not necessary to perform all functions.

Blanking simulation is rarely done with a “solver” in a production environment. Blank definition and meshing is generally done in the preprocessor. The analyst simply generates mesh for a predefined blank boundary. Alternatively, a mesh for a rectangular blank is created first. Then, the blank mesh is trimmed using the blank boundary line. Most users prefer the first method because it is simpler. The second method, however, gives the analyst a mesh pattern lining up with some reference points that could be useful for validation and correlation.

Springback is the result of stress relaxation. The springback analysis in step 5 is often skipped to save time. The reality is that springback occurs automatically as soon as the die opens. In some areas of a complex automotive part, the stresses cannot be totally released, or the stresses will release to a different pattern due to the constraint of the addendum. Further springback will occur when the addendum (working like a rubber band providing extra constraint) is trimmed away. The importance of this extra step may be case dependent.

Besides the functions listed previously for a complete line die simulation, it is necessary to perform additional numerical work for accuracy

and performance. A trimmed mesh often leaves “bad” elements around the trimmed boundary. Those elements can be classified into three categories (Fig. 14) that may lead to problems in the subsequent analysis:

- Improperly defined elements
- Triangular elements with bad aspect ratio
- Small elements

The first category can be easily identified. When a corner of a quad element is cut away, the remaining element has five nodes (Fig. 14a). Bad triangular elements (Fig. 14b) are too stiff and often influence other elements surrounding them in the subsequent analysis. Small elements (Fig. 14c) will slow down the calculation efficiency for dynamic explicit codes. It will also cause the stiffness matrix to be ill-behaved, leading to slow convergence or even divergence for static implicit codes. All three cases are undesirable and must be remeshed for good results.

In a real die lineup, the line dies (the second stage through the last stage) often do not line up with the first draw die operation for various reasons. Hence, it is necessary to reposition the panel from stage to stage so it will fit into the die properly. This creates two issues that analysts should be aware of. First, the residual tensors cannot be rotated like a rigid body. Second, the sprung part may cause some initial interference with the prepositioned die members or components. Those die members must be repositioned, and the travel must be adjusted accordingly.

Alternatively, the job can be set up by repositioning die members of the subsequent operations without changing the sheet metal. This may take care of the tensor rotation problem, but it is not necessarily simpler. The motion of the moving piece will move in a user-defined local coordinate system, not in the global z-direction.

**Job Setup.** Setting up a stamping simulation today (2006) is quite different from what was done ten years ago. Most codes have an integrated process definition tool built inside the preprocessor. The tool does much more than a generic preprocessor such as Hypermesh (Altair Engineering, Inc.).

A complete input deck is very complicated, with many types of keyword control cards. It may be overwhelming for new users. It will be helpful to group the keywords into several categories.

**General Job Definition.** In this section, job title, comments, and external files are defined. In addition, the global job controls, including termination criteria, time-step control, and adaptivity, are also defined.

**Parts Definition.** All parts used in the simulation are defined, including material model and data, metal thickness, rigid body and constraints, and element type for the sheet metal.

**Interface Definition.** All contacts between the sheet metal and each die member need to be

defined properly, including the friction. Sometimes, it may be necessary to define contact between die members and guide pins to ensure proper movement.

**Boundary Conditions.** This section covers five categories:

- Draw beads
- Binder or pad pressures (or forces)
- Prescribed motions of die members
- Nodal constraints (e.g., symmetry or weld lines)
- Supplemental external pressure (used in hydroforming, superplastic forming, and other unconventional forming methods)

**Numerical Controls.** This section defines miscellaneous parameters that may influence the results, such as hourglass control, contact-related parameters (e.g., penetration tolerance), convergence tolerance, solver selection, and controls.

**Output Controls.** This section defines the specific output desired, including type of information (e.g., thickness and plastic strain), frequency of the output, and other details (such as integration points).

**Auxiliary information** also needs to be defined, depending on the complexity of the job. The most common ones are the curves, vectors, and coordinate system:

- Curves for information such as the constitutive relation for the material, prescribed motion curves (such as displacement or velocity), and force or pressure as a function of time
- Vectors that define the direction of motion (commonly used in line dies to define the cam trim and cam flange actions)
- Coordinate system that defines material orientation (needed for some complex material models)

Although most software define everything through a graphic user interface, it is still helpful for a novice user to understand this to make sure everything is properly defined. Sometimes, the default value defined may not be optimal. Experienced users need to have a comprehensive understanding of the job setup to make the best decision for an optimal job setup.

**Fig. 14** Undesirable elements from trimmed mesh around a boundary. (a) A cut corner on a quad element results in a remaining element with five nodes. (b) Bad triangular elements are too stiff and often influence other elements surrounding them in the subsequent analysis. (c) Small elements slow down the calculation efficiency for dynamic explicit codes.

**Boundary Conditions.** A good setup must define these conditions accurately, not as a numerical tool to influence the results. It is important to define all the boundary conditions according to the physical setup. In metal-forming simulations, those conditions are usually similar and contain one or more of the following items:

- Punch travel (or die travel)
- Binder travel or force
- Draw bead
- Pad force or pressure
- Symmetrical (or other additional) constraints and blank locators or guides
- Cam or other moving element travel
- Auxiliary pressure (used in superplastic forming or hydroforming)

Not all of the items listed previously are used in a single simulation. The most common boundary conditions for a stamping simulation are the first three items in the list. It is important to model both the binder and punch (or die) movement as accurately as possible, because it may affect the binder wrap and how the sheet metal comes in contact with the die members. A good model requires:

- Accurate initial position of all die members (i.e., punch, die, binder, etc.)
- Accurate blank gaging and guides
- Gravity loading of the sheet metal
- Binder travel control (in a toggle press) or binder force (in an air-draw or transfer press)
- Punch travel (in a toggle press) or die travel (in an air-draw or transfer press)

**Punch Travel Control.** There are two different types of presses used for metal forming: mechanical and hydraulic. The ram velocities of these presses have very different behavior. Hydraulic presses are slow and therefore are seldom used in production. However, they are widely used in tryout for their versatile control ability. The ram velocity of a mechanical press basically moves following a sinusoidal pattern. Figure 15 shows the ram velocity and the location of the ram relative to the bottom dead center of a typical production press used in the automotive industry.

The travel can be defined using a prescribed displacement or velocity curve. The advantage of using a displacement curve is the accurate control of the location of the die members (e.g., punch). However, a simple linear displacement curve will implicitly define the punch to move at a constant high speed (as shown in "A" in Fig. 16). It may induce unwanted stress noise in the beginning and end of the operation. Hence, it is common to use a velocity curve to define the motion of the punch.

It is obviously incorrect to model the motion of the punch or the die with one-half of the sine wave. The actual velocity or displacement profile during the entire forming process is only a small portion of the sine curve that is closer to a linear line that continuously decreases to zero at the end of the forming process. However, there

are two problems with modeling the punch with such a curve. High velocity at contact often causes large disturbances that may deteriorate the solution quality. Continuously decelerating the punch in the duration of punch contact will increase the CPU time with a dynamic explicit code. It generally does not improve the solution

quality that much. Figure 16 illustrates some popular curves used for prescribing the punch motion.

Some software packages have developed a built-in feature to make this easier. The user just specifies the maximum punch speed ( $V_{\max}$ ) and the ramp-up time ( $T_{\text{rise}}$ ) needed to increase from

Fig. 15 Displacement and velocity curves of a mechanical press

Fig. 16 Typical velocity profiles used for tamping operations

zero to  $V_{\max}$ . A curve as shown in the graph on the left of Fig. 17 will be generated and used as the prescribed velocity profile for the punch. Some software even allows the user to specify the ramp-up speed ( $V_r$ ) as the percentage of the maximum speed to control the transition, as shown in the graph on the right of Fig. 17. When  $V_r$  approaches, it becomes a trapezoid, as shown in "F" in Fig. 16. It is interesting to know that the total travel time ( $T_{\text{total}}$ ) needed is always governed by the following equation for the profile patterns "F" and "G," regardless of the parameters chosen:

$$D_{\text{travel}} = (T_{\text{total}} - T_{\text{rise}}) \times V_{\max} \quad (\text{Eq 15})$$

Note that neither profile shown in Fig. 17 describes the real movement of the punch (shown as the shaded area after the point of contact in Fig. 15). However, they are much faster than the real punch and do not deteriorate the results. Even the simple curve "F" (Fig. 16) gives relatively good results.

**Drawbead Modeling.** Draw beads are used in the majority of stamping operations. The beads are generally narrow (5 to 10 mm, or 0.2 to 0.4 in.), with two to four radii in its cross section. To model the actual bead shape for sheet metal to flow through is practically unfeasible for two reasons. First, the element size has to be less than 1 mm (0.04 in.) in the beginning. That will require extremely long CPU hours for both the binder closure and draw-forming simulations. However, it is becoming possible today (2006) with the advancement of MPP technology and the availability of low-cost high-speed CPUs. The other challenge is the reliability of the shell element used today (2006), when the size of the element becomes a fraction of its thickness. The results, especially the stress distribution, may be questionable. This approach provides an opportunity to better capture the deformation in several ways, such as the wrinkling gathered at the end of the bead.

Most popular codes developed the "line" bead in the mid-1990s. The user simply needs to provide a curve representing the center line of a bead segment instead of the true bead shape. As the sheet metal is being drawn into the die cavity, the nodes in the binder may flow across the bead line. External force will then be applied to those nodes. The force is either directly specified by the user or calculated from a more sophisticated equation. The equation could be a function of contact pressure, coefficient of friction, or other parameters.

The force vector could be in the direction against the motion of the node. It is argued that the force vector should be normal to the bead line and the magnitude should be reduced. A hybrid model may work better. However, it is not easy to verify which model really works better.

The line bead model is a big improvement over the nodal force model used in the past. First, it is much easier to set up. Second, it is much more realistic, especially for deep-drawn parts. Third, it is much more efficient than modeling

the real bead shape. It served the industry well for many years. However, as the industry shifts its focus from splitting and wrinkling prediction to springback, binder force, and sidewall curl prediction, line bead is a source of the accuracy problem.

## Important Technical Issues

**Units.** All FEM codes use dimensionless numbers for input and calculation. However, all those numbers carry implicit dimension throughout the calculation. Hence, the units of all input numbers must be consistent to ensure meaningful results. A simple check is Newton's second law of motion ( $F = ma$ ). Hence:

$$1 \text{ force unit} = 1 \text{ mass unit} \\ \times 1 \text{ length unit} / (1 \text{ time unit})^2$$

All derived units must be based on the basic units. Hence:

$$1 \text{ stress or pressure unit} = 1 \text{ force unit} / \\ (1 \text{ length unit})^2$$

$$1 \text{ density unit} = 1 \text{ mass unit} / (1 \text{ length unit})^3$$

$$1 \text{ energy or work unit} = 1 \text{ force unit} \\ \times 1 \text{ length unit}$$

The popular units used around the world in CAE, including metal-forming simulation, are not standard centimeter-gram-second, meter-kilogram-second, Système International d'Unités (SI), or U.S. customary. It is a mixed

system that meets the needs of several considerations. Table 3 shows the systems that may be selected for use in an FEA model.

The first two systems are very popular among most types of CAE simulations. They are chosen because almost all geometry-related information such as the mesh models use millimeters. Many dynamic simulations use milliseconds, making the first system popular among analysts doing crash simulation. Many prefer the second system, because much of the test data uses MPa as the stress unit. Table 4 gives some common numbers used in a simulation that may help the user keep consistent units.

**Integration Time Estimation for Dynamic Explicit Codes.** Because dynamic explicit is the dominating code type used in sheet metal forming simulation, it is worthwhile and necessary to understand the CPU time needed for an analysis. The total CPU time needed for a job with the explicit integration method can be estimated using the following equation:

$$\text{CPU} = N_{\text{cy}} \times T_{\text{zc}} \\ = N_{\text{cy}} \times N_{\text{el}} \times \bar{t}_{\text{zc}} \quad (\text{Eq 16})$$

where  $T_{\text{zc}}$  represents CPU time per zone cycle. It stands for the CPU time needed to process all elements per time step (or cycle). It is software and hardware dependent. Different versions of the same software may perform differently on different hardware platforms due to different compiling or system optimization.

The variable  $T_{\text{zc}}$  also depends on  $N_{\text{el}}$  (the total number of elements used for the deformable sheet metal) and  $\bar{t}_{\text{zc}}$  (the average CPU time

Fig. 17 Smoothed curves used in a forming simulation.  $V_{\max}$ , maximum punch speed;  $V_r$ , ramp-up speed;  $T_{\text{rise}}$ , ramp-up time

Table 3 Summary of the units used for finite element modeling analysis

System	Mass (M)	Length (L)	Time (t)	Force (F)	Stress/pressure ( $F/L^2$ )	Energy ( $F \cdot L$ )
CAE-1	kg	mm	ms	kN	GPa	kN · mm
CAE-2	tonne	mm	s	N	MPa	N · mm
CGS	g	cm	s	dyne	dyne/cm <sup>2</sup>	erg
CGS—	g	mm	ms	N	MPa	N · mm
SI	kg	m	s	N	Pa	Joule
U.S.	lbf · s <sup>2</sup> /in.	in.	s	lbf	psi	lbf · in.

Note: CAE, computer-aided engineering; CGS, centimeter-gram-second; SI, Système International d'Unités

needed per element). For the same element size,  $N_{el}$  is roughly proportional to the size of the blank. Conversely,  $N_{el}$  is inversely proportional to the mesh density for the same blank size. The relationship can be expressed as:

$$N_{el} \propto W \times L / l^2 \quad (\text{Eq 17})$$

where  $W$  is the width of the blank,  $L$  the length of the blank, and  $l$  (or  $h$  by  $w$ ) the size of the element. Thus, the total number of elements could be quadrupled (assuming uniform mesh) when the element size is reduced to one-half of the original size. Therefore, a large-sized job or a dense mesh will take a considerably longer time to calculate.

The variable  $N_{cy}$  in Eq 16 is the total number of cycles (or time steps) needed to finish the job. It is approximately governed by the following equation (assuming constant time step):

$$N_{cy} = T / \Delta t \quad (\text{Eq 18})$$

where  $T$  is the total travel time, and  $\Delta t$  is the time step. The total travel time depends on travel depth  $D$  and the tool speed  $V$ , as described in Eq 19. (The equation would be exact if the speed remains constant. If users choose to gradually ramp up the die to the target speed or decelerate the die down to zero near the end of the stroke, the total time will be a little longer.) Therefore, deep draw panels such as dash panels and door rings will take considerably more CPU time than shallow panels such as roofs:

$$T \propto D / V \quad (\text{Eq 19})$$

The time step ( $\Delta t$ ) used in the dynamic explicit code is a complex issue. When the time step is too large without any special treatment, the job will become unstable. Using a small time step will increase the CPU time significantly. The maximum stable time step,  $\Delta t_{cr}$ , in an analysis can be described by:

$$\Delta t_{cr} = \min(l_{ch} / C) \propto \min\left(l_{ch} \times \sqrt{\frac{\rho}{E}}\right) \quad (\text{Eq 20})$$

where  $l_{ch}$  is the characteristic length of the element,  $C$  is the wave speed,  $\rho$  is the density, and  $E$  the Young's modulus of the sheet metal. For a two-node bar element, the characteristic length is the length of the bar element. Hence, the critical time step ( $\Delta t_{cr}$ ) is approximately  $2 \mu s$  for a steel bar element of 10 mm (0.4 in.) in

length. The characteristic length for a four-node shell element is not that straightforward. For a rectangular shell element, it is the length of the shortest side. Additionally,  $\Delta t_{cr}$  in Eq 20 needs to be modified to consider the material bulk modulus. The actual initial time step used in the code is slightly more conservative to ensure stability.

The variable  $\Delta t$  in Eq 18 is governed by the smallest element of all elements in the model. Hence, a single small element will slow down the entire calculation. Similarly, if an element is severely distorted due to either stretching or wrinkling, the minimum  $l_{ch}$  (and  $\Delta t_{cr}$ ) could be reduced significantly. This will lead to a substantial increase in CPU time.

Thus, by combining all of the previous equations, the total CPU time needed for the simulation can be estimated by:

$$\text{CPU} \propto N_{el} \times \frac{D}{V} \times \sqrt{\frac{E}{\rho}} \times \frac{1}{\bar{\mu}_{ch}^{\min}} \times \bar{t}_{zc} \quad (\text{Eq 21})$$

It is obvious from the previous equation that CPU time is strongly influenced by many factors. Hence, comparing CPU time between two cases without any information on the details, such as the mesh density, is totally meaningless. Finer mesh normally produces better results. However, fine mesh will require much longer CPU time. If the elements are uniformly reduced to one-half of the original size, the CPU time will increase up to 800%! Analysts must find the balance point to obtain an acceptable solution within reasonable time.

This equation is only a general guideline. The actual CPU time will be much longer because the smallest characteristic length is changing throughout the entire process. It is also much more difficult to estimate CPU time if adaptivity is used. Although the general principle still applies, the number of elements grows continuously throughout the analysis.

## Metal-Forming Simulation Applications

For decades, stamping manufacturers have used their experience and knowledge to create the die face. After completion of each die design, actual die would be made, followed by the use of trial and error to troubleshoot the die set for

stamping defects such as splitting, wrinkling, and shape changes.

Forming simulation allows tool designs to be validated virtually by using incremental FEM on a computer before any tool steel is cut, which saves costly reworks that used to occur after the tool was finished. For instance, forming simulations can predict splitting (Fig. 18). In one case, for example, by adjusting the draw bead in the forming simulation of a drawn fender, it was possible to resolve a splitting problem. In addition to troubleshooting in splitting, forming simulation is also proven to be efficient in checking for other stamping defects, such as surface and shape defects. For example, the mean stress and thinning distribution from forming simulations can be used to spot potential surface defects, thus helping tool and die makers to troubleshoot potential problems on the part before the tooling is made and to make adjustments on toolmaking accordingly (Fig. 19).

In recent years, forming simulation applications have grown enormously as the benefits of troubleshooting and optimizing processes through the computer rather than through extensive shop trials have been realized. The rapid development of software technology, together with faster and lower-cost computer hardware, has enabled many metal-forming operations to be modeled cost-effectively.

## Metal-Forming Simulation Systems

A typical CAE simulation begins with the geometry given and boundary conditions well defined. The analyst's job is to set up the model as defined, run the job, and compare the results against a predefined failure (or pass) criterion. Metal-forming simulation is very different from CAE simulations in any other field in several ways. First, the geometry given is only the product data and not the die face. In a large company, the die face could be designed by specialized die layout personnel using a CAD system with some special die-face design functions. Often, it is the analyst's job to create the initial die-face.

Second, the boundary conditions (binder force and bead force) are not defined either. Hence, the analyst must go through an iterative procedure to determine the optimal boundary conditions and die-face design that will make a formable part. Third, the process necessary to make a sheet metal part (especially for an automobile) may need to be defined. An experienced analyst must have the knowledge and proper tools to redefine the die operation lineup.

Generally speaking, a good metal-forming system should have all the special-purpose modules listed in Table 5 so that the analysts can do everything within a single system. The so called preprocessor for metal forming does more than the traditional ones that primarily perform mesh creation, editing, and model organization. It must have the ability to do die creation and process definition.

**Table 4** Typical properties for each system (see Table 3 for base units of mass, length, force, and time)

System	Density of steel ( $M/L^3$ )	Young's modulus of steel ( $F/L^2$ )	Gravity ( $L/t^2$ )	Velocity ( $L/t$ ) (35 mph)
CAE-1	7.830E-06	2.070E+02	9.806E-03	1.565E+01
CAE-2	7.830E-09	2.070E+05	9.806E+03	1.565E+04
CGS	7.830E+00	2.070E+12	9.806E+02	1.565E+03
CGS-	7.830E-03	2.070E+05	9.806E-03	1.565E+01
SI	7.830E+03	2.070E+11	9.806E+00	1.565E+01
U.S. customary	7.330E-04	3.000E+07	3.860E+02	6.160E+02

Note: CAE, computer-aided engineering; CGS, centimeter-gram-second; SI, Système International d'Unités

As analysts' jobs become more versatile, the system (including the solver) should be able to handle a variety of functions, including:

- Stamping (draw forming or crash forming, toggle draw or air draw)
- Bending or flanging
- Trimming, piercing, or hole expansion
- Sheet hydroforming (fluid forming)
- Tube multibending
- Tube hydroforming
- Springback

Some additional functions are highly desirable as the industry becomes more sophisti-

cated and vertically integrated. Those functions include:

- Blank estimation
- Blank nesting
- Draw bead optimization
- Trim line optimization
- Smart binder and die-face creation and optimization
- Smart springback reduction
- Automatic pressure control for tube hydroforming or superplastic forming
- Automatic binder-force control
- Deformable binder

- Special forming operations such as hemming, superplastic forming, warm forming, roll forming, and rotary forming

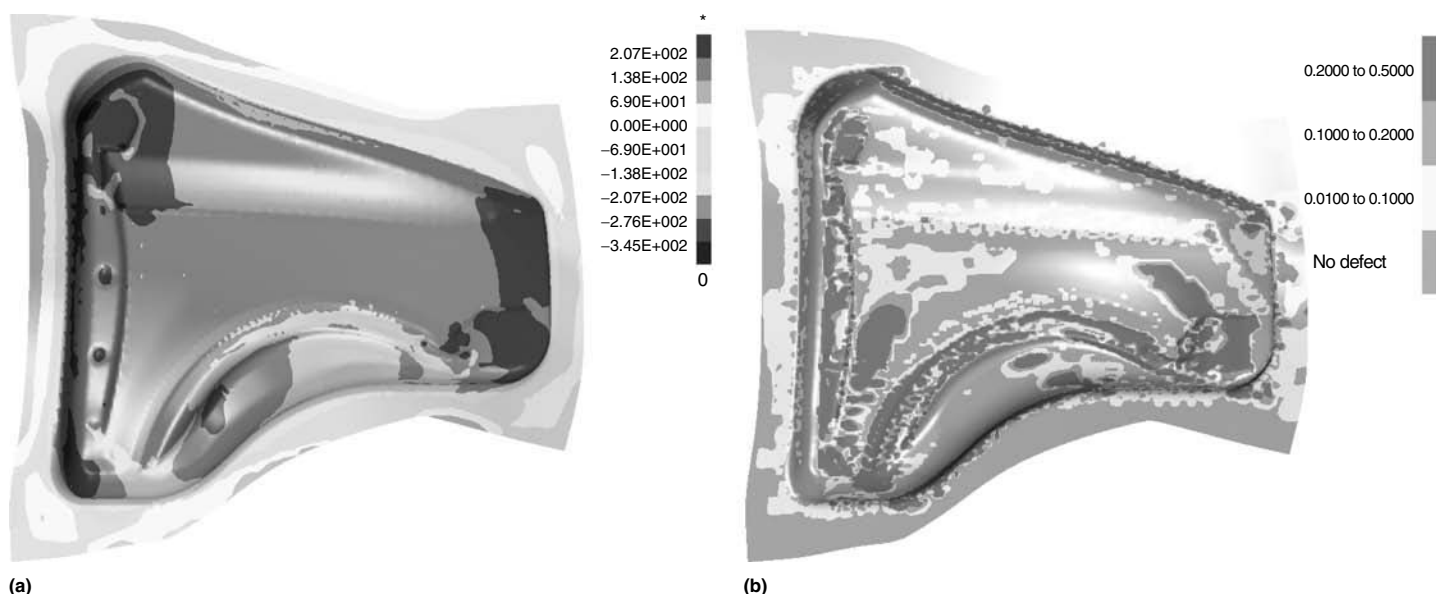

## Forming Software Overview

The following sections review the capabilities of three major systems that are popular among sheet metal forming users worldwide:

- AutoForm, developed by AutoForm Engineering (Switzerland)

**Fig. 18** Illustration showing thinning of drawn fender from NUMISHHET 2002 benchmark. (a) Split. (b) No split. Courtesy of Engineering Technology Associates, Inc.

**Fig. 19** Illustration showing (a) mean stress distribution and (b) stoning distribution of drawn fender of NUMISHEET 2002 benchmark. Courtesy of Engineering Technology Associates, Inc.

- PAM-STAMP 2G, developed by the ESI Group (France)
- Dynaform, developed by Engineering Technology Associates, Inc. (United States) using LS-DYNA, developed by Livermore Software Technology Corporation (United States) as the solver

Each software vendor has a particular strategy in developing their system.

**PAM-STAMP 2G** is one of the leading software systems designed specifically for sheet metal forming. The following sections provide an overview of this system based on information supplied by the ESI Group.

*Virtual Stamping Software.* The need for an integrated and scalable software for stamping, covering the entire design process from part design through die design and die evaluation, tuning, and validation of the process, is the basis for PAM-STAMP 2G. This system allows users to make decisions on-line in a continuous improvement process in a collaborative environment that connects the design engineer, the material provider, the die designer, and the try-out press shop from an early stage of the design until the production. PAM-DIEMAKER gives the design engineer the flexibility to quickly test die geometry in the initial phases, and PAM-QUIKSTAMP enables the selection of the material properties. Lastly, PAM-AUTO-STAMP focuses on part quality in the final stages of the process simulation. Each step can be iterated many times to progressively improve quality throughout simulation process without any discontinuity.

Table 5 Special-purpose modules for optimal metal-forming system

Module	Features
Preprocessor	Computer-aided design interface Computer-aided engineering model reader and writer Automeshing Model creation and editing Model morphing Complete process definition Die-face and binder creation Automatic positioning Draw bead generation Deck builder
Solver	Job submission and queuing Execution
Postprocessing	Review results (3D fringe pattern, section plots) Animation Formability assessment Surface-quality evaluation Model comparison
Special functions	Blanking and trimming with auto-remeshing Intelligent mesh coarsening Automatic morphing for springback compensation Results mapping Built-in material database supporting popular models Model reposition

To fulfill the new requirements, the solver was re-engineered in a new architecture with object-oriented native MPP structure, with a new data model especially designed to manage simulation data across different applications and over time. Each application has a weak link to customer applications through the use of universal files (international graphics exchange specification or visual data analysis) or strong links through application program interfaces that allow plug-ins directly to a customer's database and/or data models as special customization. All of these modules are accessible through a single graphic user interface.

The different modules allow a complete stamping simulation in one consistent environment. Integration of the modules resolves numerical transmission issues, which saves time and allows the user to focus on stamping issues instead of numerical issues. The user can simply import a CAD file and simulate the forming process step by step, from die design to an initial evaluation, then tuning and final validation.

*Die-Face Design.* Most commonly, a project is started with only the CAD geometry of the component. The CAD geometry is read into the program, which treats and repairs the surface data and automatically produces a clean and connected mesh. The newly imported part geometry needs to be prepared in order to serve as a reference for the die design (Fig. 20). During this part-preparation phase, the geometry will be checked for eventual problems, and eventual holes will be closed.

Flange-specific treatment allows the user either to automatically eliminate them or to hide them in order to use them as reference geometry for blank development later on. Furthermore, the user can smooth the part edge by using a rolling cylinder technology. Next to that, if the part geometry has a symmetry plane or is built as a double part, this can be defined as well.

Normally, when reading part geometry from a CAD file, this geometry is positioned in the car coordinate system (global system). Therefore,

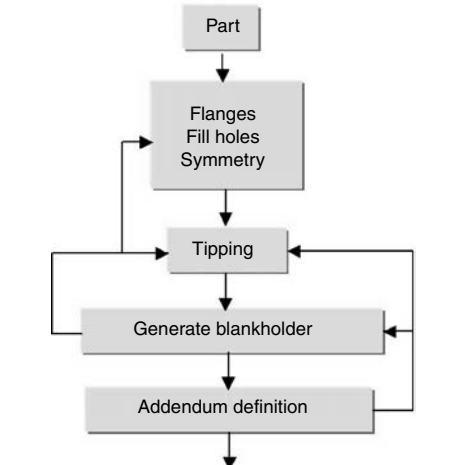

Fig. 20 Die-face design overview

it is necessary to define a local system that can serve as a reference for the stamping direction and also has the ability to automatically detect the optimal stamping direction based on several criteria, such as the minimum draw depth. The resulting local system can (if necessary) be further modified by manually adjusting the system.

Once the part geometry is prepared, the tool design can start with an initial design of the binder surface (Fig. 21). The code has complete and intuitive functions for generating binder surface in three different methods. The user can define the binder surface using parametric profiles and sections, define the binder surface using theoretical surfaces (fitting of flat, cylindrical, or conical planes), or import an already existing surface from a CAD file. Depending on the chosen method, the binder surface can be visualized and modified in 2D and 3D simultaneously and interactively. There are also several options for verifying the binder design, such as checking the depth of draw (relative to the binder surface) or the developability of the surface.

The user can start building addendum using 2D profiles (Fig. 22). The code provides fully interactive functions that allow the user to easily position each profile. When the profiles are attached to the part geometry, they can be further

Fig. 21 Binder definition by section approach

Fig. 22 Addendum design by profiles

modified by changing the orientation, resizing, extending, or shortening each profile.

The 2D geometry can be modified as well, with full control over all the parameters that construct the profile, such as angles, radii, heights and distances, and tangency. By dragging and dropping the control points of the profile, users can interactively modify the parameter values. Modifications in 2D are immediately visible in 3D, thus further enhancing the interactivity. This method is especially useful in conceptual design. The user has full control of 2D parameters by defining all parameters manually (Fig. 23). The user can also modify the design interactively. Finally, the different profiles can be saved in the database for future modification.

When all profiles are defined, the user can visualize the die entry line. This line is automatically created and can be modified manually. Once the profiles and die entry line are satisfactory, the 3D surfaces can be generated in order to have a global view of the entire tool. The 3D surface information is useful for visualization purposes and early anticipation of problems such as tangency.

**Quick Evaluation.** When a die design is generated (Fig. 24), the design must be checked for formability using PAM-QUIKSTAMP based on optimal hybrid formulation of explicit/implicit solvers with uncoupled membrane-bending formulation. This rapid simulation allows the user to quickly evaluate the die designs early on in the simulation process, using the extended material database and a consistent

elastoplastic material model in order to simulate the blank behavior.

In addition to the binder surface and the run-off design, several process parameters can be assessed, such as the blank-cutting pattern and material, draw bead forces and positioning, and so on. All of this information can be defined and modified within the graphic user interface. Such evaluation is useful to enable decision-making early in the design process and eliminate erroneous choices (Fig. 25). However, more accurate analysis for tuning and final validation is done using the incremental solver.

Usually, the result of the forming simulation will be a plot of the deformed geometry. On top of this geometry, the user can plot iso-values such as the thickness, thickness strain, stresses, FLD, and so on. In case the forming simulation shows problems due to the die design, one can return to the PAM-DIEMAKER module and perform the appropriate changes.

It is possible to make changes in the binder region without touching the rest of the profile definition. As the binder surface is modified, all profiles will just follow the newly created binder surface. It is also possible to iterate on the profile definition itself and add or remove several profiles to the existing die design.

In cases where the die-face surface was created in a different CAD package, another method to modify the die geometry is possible by using the morphing technology (Fig. 26). This

technology allows the user to manipulate the mesh in 3D by defining feature lines and feature nodes, which is especially useful if no parametric profile data are available. One very common (and useful) option of morphing is the modification of the radius of already existing fillets. Another example would be the opening of a die wall by changing the angle. It ensures the tangency and enables the export of the modified surface in order to upgrade the original CAD data. The integrated package will allow the user to progress in upgrading the stamping process design in a continuous-improvement environment without any modeling discontinuity.

**Tuning and Validation.** The entire process is validated using an incremental solver. PAM-AUTOSTAMP is based on a shell-element formulation with both incremental explicit and implicit solvers. Different forming stages are simulated through a sequence of data selections using the data model and object structure. The model upgrade and the data transfer from the quick solver to the incremental solver occur smoothly without any modeling process discontinuity. Both solvers share the same mesh type and requirements and the same material model and database. Consequently, the user is able to focus on solving the stamping problems without any model perturbation and artificial numerical issue related to program interfaces.

Solvers have been developed for sheet metal forming to give users details on stresses, strains, and contact phenomena. The full history of the sheet metal is simulated, taking into account blank-tool interaction (blankholders, support systems, locator pins, draw beads, trim tools, etc.), which is a pre-requisite to capture all the physics that influence the final panel quality and geometry after trimming, springback, and flanging. Figure 27 is an example of a simulated part after trimming.

After the tool design has been completely checked and iterated upon, the surface information can be used as a reference for further CAD work in order to develop a final class A surface (Fig. 28). This export operation can use either international graphics exchange specification or visual data analysis format.

**Computer-Aided Die Shape Compensation.** Springback prediction has been a matter of

Fig. 23 Details of parametric bulge profile

Fig. 24 Initial die-face design

Fig. 25 Die-face design iteration

Fig. 26 Typical radius ( $R$ ) morphing

Fig. 27 Simulated final part after trimming

interest for many years, but it has only become very useful in recent years. Prediction of springback is also only part of the problem. The difficulty lies with the proper use of the prediction. How to make corrections to minimize or even eliminate springback is the real challenge for die engineers and technicians, just as accurate prediction of springback is a critical step in the procedure. A few years ago, simulation results were not considered reliable enough to modify tooling for springback compensation; today (2006), however, with recent significant improvements in the reliability of the predictions, there has come the necessary investment in developments for simulation-based die shape compensation.

Predictive springback compensation is an important tool with the increasing use of advanced high-strength steel. In many cases, where components are to be conventionally pressed but with materials with yield strengths up to 1200 MPa (174 ksi), the magnitude of distortion due to springback is significant enough to make it impossible for corrections by re-striking or overbending alone. Remachining the die face without reliable data is nearly impossible, and required tool changes may involve insertions, at a minimum, or, worst case, entirely new base castings if simply not enough cast material is available to achieve the changes in shape that may be required. This problem is significant if discovered during physical tryout.

PAM-STAMP 2G includes a module for iterative die compensation for springback. It modifies the die shape automatically, avoiding undercuts and maintaining the necessary smooth blankholder shapes without the need for any user input at all. It will also iterate, checking the results of the new forming and springback calculations until an optimized result is obtained. Typically, between three and six iterations are used to obtain the optimal die face.

The tool shape-compensation methodology existing today (2006) is based on modifications to the mesh of the tool. While this is certainly the best approach for performing iterative loops within a simulation-based environment, it

still leaves the problem that, at the end of the compensation process, the user has a modified mesh of the tool, whereas he really needs a CAD model. In order to address this issue, work with surfacing specialists is being done to transform the modified tool meshes back to CADs ready for machining.

**Tube Forming Simulation.** Tubular hydroformed parts are beginning to account for a significant proportion of a typical vehicle structure, and with this comes an increase in the need for accurate simulation of this process. Tube forming follows a similar engineering evolution to conventional stamping, with some specific requirements.

PAM-TUBE 2G has been developed to perform a die design and forming simulation system for tube bending and tube hydroforming. It contains a similar mix of modules to address process design, tool design, fast feasibility, and accurate validation for tubular parts.

The die design module handles the design of any necessary prebending operations, including determination of the bending line, creation of bending tools, and an automatic creation of the data setup for an accurate bending simulation. The solver includes advanced tube-specific functions, such as an ovalization prediction module. The incremental solver provides the detailed validation of both bending and hydroforming processes.

**LS-DYNA and DYNAFORM.** LS-DYNA is based on DYNA3D, which was developed by John Hallquist at the Lawrence Livermore National Laboratory. The earlier applications of DYNA3D were primarily for the stress analysis of structures subjected to impact loadings. Hallquist later founded Livermore Software Technology Corporation (LSTC) to develop LS-DYNA for commercial applications. The vision of LSTC is to develop a single code with capabilities to solve a variety of problems involving multiphysics that may require multistages, multiprocessing, and multifunctions. Applications include crash/safety, drop test, and metal forming for a wide range of industries.

LS-DYNA is a general-purpose FEM code with a huge collection of element technology, contact models, and material models, among other FEM technology. Although it started as a dynamic explicit code, LS-DYNA has developed many efficient linear equation solvers and non-

linear implicit solution algorithms. Because of this built-in feature, solver schemes can be chosen by the user and seamlessly switched as desired. This allows complex problems such as a multistage stamping to be solved with a single code. Analysis can be done with the dynamic explicit solver primarily for forming and flanging operations. An implicit solver can be used for binder wrap and springback for better accuracy. However, LS-DYNA is only a solver. It relies on third-party software to provide the complete system solution. Among them, the most popular is DYNAFORM of Engineering Technology Associates, Inc. (ETA). The following sections provide an overview of this system, based on information provided by ETA.

**Implementation and Impact of Stamping CAE.** Computer technology for CAD and CAE has had a tremendous impact on the tool and die industry. Long before the implementation of CAE in the tool and die industry, CAD was adopted to create 2D and 3D die designs. However, the approach resulted in poor die design and caused many unforeseen problems during tooling tryout.

The traditional stamping manufacturing process employs CAD during the die design phase. (Fig. 29). Upon the completion of die design, the die construction is carried out, followed by the tooling tryout to troubleshoot the new die set for major stamping defects. If the die produces parts with no stamping defects, it will be sent to the stamping plant for stamping production. On the other hand, if splitting and wrinkling are spotted during the tryout, the die set needs to be reworked. Occasionally, the die set is scrapped, and a new die design is needed. As a result, the die manufacturing time is increased as well as the cost of die making.

The advantage of stamping CAE (Fig. 30) is to effectively reduce the major stamping defects prior to the die design and construction, thus optimizing the die structure design and material use. As shown in Fig. 30, the stamping CAE, including forming simulation, die-face engineering, blank-size engineering, die structural analysis, springback compensation process, and line-die simulation, are introduced to the stamping manufacturing process to achieve product manufacturing, quality, and cost-saving through optimized product and process design.

Fig. 28 Typical validated tool geometry export

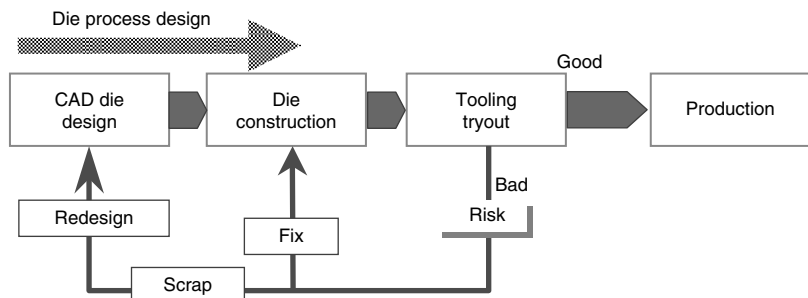

Fig. 29 Flow chart of traditional die try-out process

*Die-face engineering (DFE)* is a CAE-based tool developed for stamping engineers to quickly derive a suite of draw die (including binder and addendum) from the product design in the early stage of tooling design. The draw die development from DFE is then used as a baseline for tooling design and can be used for quick evaluation of tooling and formability analysis via simulation of the forming process. By integrating with forming simulation, DFE helps to reduce iteration time for tooling design in the CAD system. It can shorten the lead times for tooling design and construction by phasing out the product-intent soft tools.

*Blank-size engineering (BSE)* is a stamping CAE tool that allows engineers to find an efficient material utilization using blank nesting and to estimate the optimized blank size of stamped parts. In today's (2006) stamping market, an efficient material utilization plays an essential role in gaining the competitive edge for stamping manufacturers. Material utilization refers to the process of reducing scrap created by the manufacturing process, which is approximately 5% of the total part scrap.

By using BSE, stamping CAE engineers are able to optimize the material utilization according to the given constraints, such as pitch, coil width, web size, and so on. An example showing the nesting layout of blank material for a fender is illustrated in Fig. 31.

As shown in Fig. 32, BSE provides an optimized nesting layout and material utilization. Furthermore, it also allows stamping CAE engineers to estimate the cost of producing a stamped part. The BSE also allows the tool and die industry to quickly provide a stamping quotation, in addition to performing quick evaluation of tooling design and optimizing blank shape.

*Die Structural Analysis (DSA)*. The integrity of the die structure has always been a primary concern for sheet metal suppliers in terms of part quality, weight, die life, safety, and cost-efficiency. A die structure lacking in structural integrity will produce poor-quality stamped parts due to the excessive deformation of the die during the stamping operation. This can affect the production of the entire assembly line. In addition, an ill-designed die structure can pose safety hazards to employees on the job during the maintenance operation and can increase the cost of die construction and maintenance. As a result, ensuring the integrity of the die structure is the key to successful stamping manufacturing.

The use of DSA as one of the important applications of stamping CAE has gained increasing application in the stamping manufacturing field since the early 2000s. It enables stamping CAE engineers to validate die design changes and quantify safety factors of die structures. Furthermore, DSA is used to optimize the die design for weight reduction, hence providing an opportunity for cost-savings. The DSA is also used to identify the root cause of die breakage during tryout and stamping pro-

duction. The benefits of DSA have provided significant values to stamping manufacturers in terms of die construction and stamping operations. An example showing the application of DSA to predict stresses and deflection of the upper die of an automotive body-side outer is illustrated in Fig. 33 and Fig. 34, respectively.

*Springback Compensation Process*. In recent years, advances in automotive manufacturing have resulted in an increasing application of lighter-gage high-strength steel and aluminum alloy sheets in automotive stampings, as opposed to the conventional mild steel grades. The application of such materials has posed

Fig. 30 Flow chart of die tryout with stamping computer-aided engineering (CAE) simulation

Fig. 31 Illustration showing blank-nesting layout of NUMISHEET 2002 fender using blank-size engineering

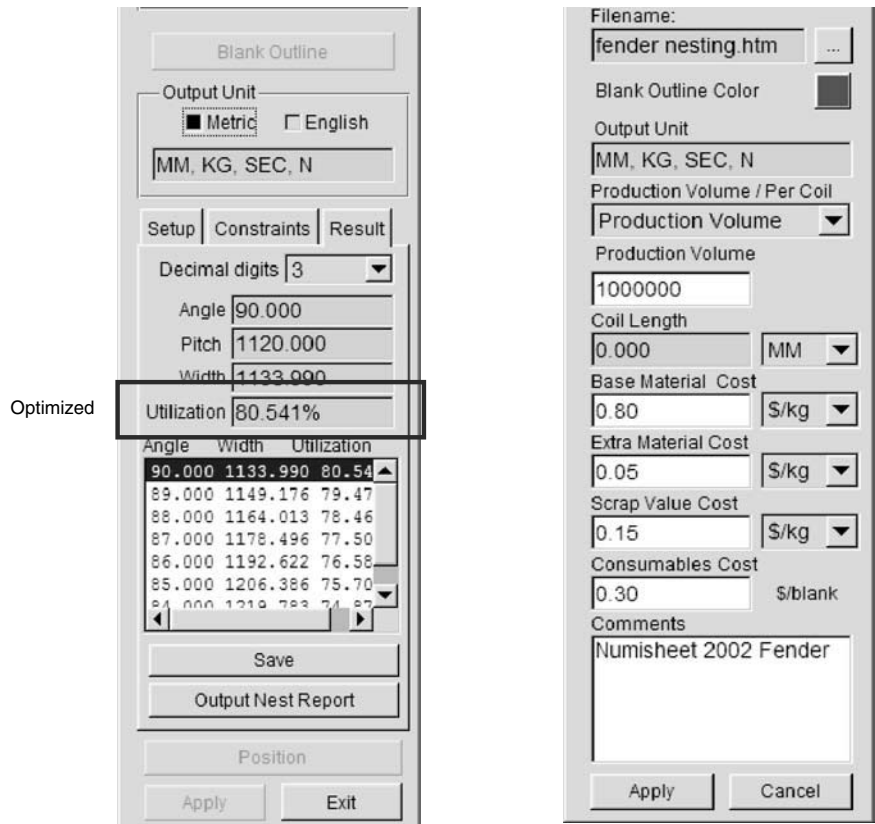

Fig. 32 Illustration showing the capabilities in blank-size engineering

challenges in sheet metal fabrication. One of the greatest challenges is springback. Springback, or shape change, is an elastic material recovery after the unloading of stamping tools and the removal of stamped parts from stamping tools. It causes undesirable final part quality and dimensional inconsistencies and creates difficulties in downstream assembly processes. In addition, it slows down new product launches while increasing changeover time and the associated cost.

**Line-Die Simulation (LDS).** In automotive stamping production, class A and B body panels are generally manufactured in three to four

operations that consist of draw, restrike, trimming/piercing, and flanging. These operations are lined up in tandem within a press line. The quality of a stamped part relies on the success of each die operation. For example, a successfully stamped fender must be formed without major stamping defects (splitting, wrinkling, surface defects) in the draw operation. In addition, the quality of the fender also relies on the trimming and flanging operations. These secondary operations must be carried out successfully without facing other stamping defects, such as recoil, flange break line failure, springback, and so on. If the die set in each operation

is not designed properly, stamping manufacturers must expend tremendous efforts to resolve the stamping defects that emerge in each operation. Such a scenario will not only affect the stamping production but also delay the subsequent vehicle assembly line. To this end, LDS saves tremendous time and monetary losses.

The application of full LDS is used to resolve stamping concerns such as formability, quality, manufacturability, and throughput requirements in each die operation, before the die sets are made. As a result, stamping manufacturers may avoid incurring extra costs during die fixing. At the present time, advanced computer technology such as MPP and faster CPUs speed up the time needed to perform a full LDS.

**AutoForm.** Starting from the product design data from a CAD system, AutoForm software evaluates the entire process and the details of each operation within a single system. In addition, product and process development within AutoForm includes an AutoForm-Sigma module for upfront assessment of the robustness of the product and/or process. All modules are integrated through a graphical user interface. The system has modules for various stages from concept design all the way to troubleshooting part production.

When a product design is finalized, it is released to the feasibility and tooling departments, who must then design an appropriate stamping die to fabricate the part. The traditional approach for die layout designers and die engineers (including die process, formability, and analysis functions) is to create or “build” the binder and addendum surfaces in a CAD system that can make the part. However, this method has the disadvantages of long lead time, high cost, and low throughput.

In terms of lead time, designing die faces in a conventional CAD system is very time-consuming. On average, it takes approximately 1 to 3 weeks to complete a draw-die development for typical automotive body panels and large inner panels. Even for small parts and structural components, several days are required.

The high cost of die development is due to the complexity of the process. Successful draw-die developments require the expertise of die engineers and analysts with many years of practical experience and good CAD skills. Almost always, they make several iterations of design modifications before finalizing a good stamping die design (e.g., changing radii, adjusting drawbars). Modifications for a typical nonparametric die-face design in a general-purpose CAD system are slow, cumbersome, and time-consuming. It is easy to make mistakes in the process, and it is difficult to study the design of different “what-if” concepts for the binder and addendum. Furthermore, when time runs out due to production deadlines, companies are forced to carry out tooling tryouts in the press, which is even more costly.

Low throughput is a limitation with a manual CAD-based approach, where CAE analysts

Fig. 33 Stress contour of upper die of body-side outer subjected to static loading. Courtesy of Engineering Technology Associates, Inc.

Fig. 34 Deflection contour of upper die of body-side outer subjected to static loading. Courtesy of Engineering Technology Associates, Inc.

must wait until the die surfaces are completed—several days or weeks—before carrying out virtual try-out simulations to check the designs for splits, wrinkles, and other stamping issues. It is far more productive and cost-effective if die-face designers or CAE analysts can immediately try out the die concepts, discard unfeasible designs early on, and concentrate on further developing of only the best design(s).

In an effort to conquer these drawbacks, several automotive companies participated in a program to develop a faster, more efficient, and less costly method for die-face design. AutoForm-DieDesigner software is the result of a development effort led by AutoForm Engineering GmbH (developers of sheet metal forming software) in cooperation with tooling departments at BMW and Audi, and with technical feedback from DaimlerChrysler and General Motors.

The software reduces tooling development time through rapid parametric design of die faces and their immediate verification and optimization with integrated stamping simulation modules. It is specialized for generating binder and addendum surfaces and for evaluating the feasibility of draw-die developments and prototype tools. Its three most important innovations are:

- Fully parametric features
- Complete integration with virtual try-out software modules
- Automatic optimizer

The parametric approach of the software is based on analytical engineering principles. It also conforms to the die engineering practice of using surface profiles (arcs, angles, and straight sections) to design die faces and is compatible with various CAD data formats. Using the software, it takes approximately 1 h to design complete die faces, starting from only the CAD surface data of the part (such as an auto fender, Fig. 35). This includes the following steps:

- Determination of tip-angle
- Filletting of sharp edges (variable radii)
- Filling of holes
- Part modifications (morphing)
- Design of the fill surface between double-attached parts
- Overcrowning
- Binder design
- Design of outer (and, if required, inner) addendum
- Unfolding of flanges
- Generation of the tools

Because all the generated die surfaces are parametric, subsequent modifications (die engineering changes) can be done in seconds or minutes. These die surfaces and simulation results can easily be exported using international graphics exchange specification, Vereinigung Deutsche Automobilindustrie Flächen Schnittstelle (German neutral file format for exchange of surface geometry), or mesh formats to

other software applications for die design, die machining, and structural and crash analysis.

**Part Design Modifications.** Almost all part designs are subject to revisions and improvements, even after official release to the die engineering department. After the parameterized binder (Fig. 36) and addendum (Fig. 37) have been created for a specific part, when the part is replaced with another (similar) part design with a modified design, the software can automatically adjust the binder and addendum accordingly. This is a time-saving feature, because it allows the original addendum and binder geometry to be reused for future design revisions of the part. In addition, automatic filleting and the ability to vary fillet radii on the part geometry save considerable time and allow virtual tryouts to be carried out earlier in the product and tooling development cycles. The initial binder surface (light background in Fig. 36) is automatically created in a few seconds, using only the CAD surface data in (Fig. 35) as input. The user can then modify the binder geometry with surface profiles.

**Parametric Linking.** With an integrated system approach and full parametric linking, all die-face designs can be evaluated with one-step or incremental simulation modules. One-step simulation results are considerably more reliable when based on the complete die face—as generated by the software—rather than on the part only. An added benefit is that these refined results are made possible earlier in the design cycle. They are available within a few minutes and include the required blank outline and various stamping feasibility criteria (Fig. 38).

The incremental module is used for high accuracy and virtual tryouts of the complete stamping process. Results include predictions of wrinkles, cracks, skid and impact lines, surface quality, and so on. Incremental tryout results are typically available within 1 to 3 h, depending on the size and complexity of the part and the desired accuracy. Additional tryouts can be launched at once because of parametric linking. For example, based on the initial results, the user can make modifications to the addendum geometry, and the various tool geometries required for the next simulation are automatically updated. Similarly, if the user modifies the punch opening line, draw bead positions are automatically adjusted.

Within a few seconds, users can change “master” global profile parameters (for example, to increase the die radius). In addition, the user can also make local surface modifications to the addendum by changing local profile parameters or directly manipulating contours such as the punch opening line, bar height, and so on (Fig. 39). A drawbar can be easily created by modifying the parameters of local addendum profiles. Figure 40 shows the complete die face for the Audi TT rear fender, created in approximately 1 h using 28 customized surface profiles.

**Formability Simulation.** From the initial die-face concept shown in Fig. 40, a quick one-step simulation may take into account the binder and addendum. Stamping feasibility results can be calculated in minutes for various stamping feasibility criteria, typically plotted in color graphics. An example plot (in black and white only from color) is shown in Fig. 41. The circled area on the left shows a risk of wrinkles on the addendum, very near to the part boundary. The circled area on the right shows a crack.

Based on one-step results, the general die concept can be evaluated early in the design cycle, and, if necessary, modifications to the part geometry can be recommended. Furthermore, the resulting blank outline can be used to design the initial blank outline for an incremental virtual tryout.

An accurate incremental analysis of the complete stamping process, using the die faces from the initial or final die face based on the one-step results, can pinpoint the formability issues more accurately. For example, the plot in Fig. 42

**Fig. 35** Part geometry (computer-aided design surfaces) of a rear fender

**Fig. 36** Automatically created initial binder surface (outer light-gray area)

**Fig. 37** View of automatically generated addendum surface (arrow), based on default profiles

(originally in color) shows the predicted thickness distribution; excessive thinning zones (originally plotted as red and yellow regions) are shown by two circled areas on the right. The simulation also shows wrinkles in the circled area on the left. These try-out results were obtained in approximately 50 min.

The die designer can then make modifications to the original die concept to smooth out the wrinkles and eliminate the cracks (for example, by changing drawbar and wall heights, radii, etc.). Furthermore, results such as wrinkling, splitting, skid mark progression, and so on can be visualized at each step of the drawing process.

**Automatic Optimization of Tooling and of the Stamping Process.** To further improve the die-face designs, the software includes an integrated optimizer module. The user first specifies the allowable ranges for tool geometry and stamping parameters. The optimizer then automatically determines the “best” design within these ranges through multiple one-step or incremental simulations to achieve the target function, for example, elimination of cracks and wrinkles, uniform surface stretching, or no excessive thinning. Tool geometry parameters include part, die, and drawbar radii; drawbar height; wall angles; overcrown; and so on. Stamping parameters

include binder forces, draw bead strength, blank outline, and so on.

Figure 43 shows the final outcome of the optimized results by adjusting parameters (such as draw bead force) defined by the analyst. The two crack zones were eliminated, and the wrinkling zone was minimized and moved away from the part boundary. Automatic optimization can help the die designer to find the best parameters for his design. It can also help the process engineer to determine the best stamping conditions.

**Stochastic Simulation for Robust Design.** Manufactured part quality and cost, as well as production timelines, can be impacted by variations in the inputs to production processes. The most carefully designed and validated product and process can lead to inadequate and/or inconsistent quality of the produced part during production due to such variations. The real challenge is to neutralize or minimize the effect of production condition variations on production quality upfront during product and process design.

Robust engineering is the concept of applying appropriate safety margins in the design of product, dies, and process conditions to accommodate worst-case scenarios in terms of a limited number of specific production conditions, such

as material and lubrication. This traditional approach in just applying safety margins is somewhat limited in scope and efficacy because it does not help develop an understanding of production conditions that is adequate for troubleshooting real-time production problems. In this regard, AutoForm-Sigma is a software module that enables robust design and engineering of stamped and hydroformed parts based on stochastic simulation technology. Simply stated, AutoForm-Sigma runs several simulations—approximately 100 simulations per run—over which uncontrollable noise parameters such as material properties, blank thickness, lubrication, and so on are automatically and randomly varied, and enables an assessment of applicable robustness metrics on the selected result(s). Rather than individual simulations with ideal inputs, AutoForm-Sigma can account for real product conditions and characterize virtual try-out results in terms of standard production quality metrics such as process capability index, scrap rate, and so on. Besides upfront manufacturing robustness assessment, this approach provides an opportunity for very early robust engineering (which “design” elements on product, die, and process design are most effective/influential in achieving specific quality desirables on a manufactured part) as well as robust design (what are the best ranges of these “design” variables).

**Benefits of Simulation.** Simulation technology enables engineers to assess product and process design from concept styling through production. In AutoForm, for example, one

Fig. 38 Typical addendum profile (dark solid line) and its defining parameters

Fig. 39 Drawbar created by modifying the parameters of local addendum profiles (black lines)

Fig. 40 Complete die face for the Audi TT rear fender

common graphic user interface provides efficient access to modules for:

- Concept styling
- Product design
- Production planning
- Process planning
- Tool design and manufacturing
- Tryout
- Production

Examples of reported savings include:

- Reduction in binder development time by 60%
- Reduction by a factor of 4 to 5 in the time from CAD part design until completed virtual tryouts
- Reduction of die-face development time from one week down to one day
- Reduction in actual die try-out time and tooling costs of nearly 50%
- Two-week reduction of tooling development time by using the generated die faces to order castings for the dies

# Summary

As the focus of die development shifts away from trial and error toward CAE simulations, the burden also shifts upfront and is undertaken more by CAE analysts. For a component to be manufactured effectively, new materials or new forming processes require a much greater degree of precision and parameterization to answer the needs of forming simulation. A customizable model that keeps track of part material history and parameters such as strain rate, kinematic hardening, and so on has become a requirement in order to attain the last 10% of accuracy at the stresses level. Therefore, the need for well-trained formability engineers with in-depth understanding of CAE technology should increase.

As an essential technology in metal stamping, stamping CAE plays a central role in the die and stamping industry. The latest stamping CAE technology enables CAE analysts to do die-face engineering, blank-size engineering, forming simulation, die structural analysis, springback compensation process, and line-die simulation. By using the technology in the early stages of tooling design, manufacturers can confidently identify costly errors before die construction begins. To that end, tool and die makers can remain competitive by producing quality dies and quality parts at a lower cost.

The full implementation of stamping CAE has impacted die and stamping manufacturers in many ways, such as troubleshooting stamping defects, improving quality, reducing toolmaking lead time, optimizing die design, and so on. The application of advanced stamping CAE technology helps manufacturers reduce tryout time and improve die-development efficiency. By using stamping CAE, substantial savings can be achieved in quality, delivery, and cost of the product. It helps die and stamping manufacturers survive in the competitive stamping marketplace. With the advancement in computer hardware and software technology, the future of stamping CAE holds even greater promise as the simulation techniques mature and expand. The output of CAE for sheet forming is also being introduced to assess part performance in service, for example, the effects of work hardening, local thinning, and so on on crash worthiness.

**Cross-Functional Analysis.** Another outcome of using the new material is the performance of the formed part. Some material (e.g., dual-phase steel) can work harden much quicker than traditional high-strength low-alloy grades. Parts may also exhibit more localized thinning due to poor formability. Both influence the behavior of vehicle crash testing. Recent studies illustrate the impact of the manufacturing pro-

cess on the component performance. Because traditional crash simulation did not take part-material history into account, simulation has not proved to be good enough to accurately predict the performance in physical testing of critical parts and subassemblies.

A study at Volkswagen revealed that, compared to real tests, simulation results were off by 21% for maximum force and 22% for part deformation if virgin material properties were used for all metal parts in crash simulations. However, an integrated analysis that kept track of part-material history (i.e., stress and strain undergone during forming), with necessary forming simulation, followed by the crash simulation proved to be much more accurate. Thus, the use of new materials has made it a requirement for stamping simulation today (2006) to maintain the full history of a part through seamless data transfer.

**Future Developments.** The CAE technology for metal forming will continue to evolve to cover more applications and with more details. In recent years, metal-forming simulation has expanded from traditional failure prediction for draw (or form) operation to springback prediction after trimming, flanging, and die compensation for the draw die. Future developments may be classified into the following categories.

**Complete Die Operation.** The CAE technology and actual applications have been rapidly maturing for several years. Future needs will drive the technology for more advancement to achieve better accuracy, capability, and

**Fig. 41** Result of a one-step simulation. The circled area on the left shows a risk of wrinkles on the addendum, very near to the part boundary. The circled area on the right shows a crack.

**Fig. 42** Result of an accurate incremental try-out simulation of the complete stamping process. Thinning zones shown by two circled areas on the right. Wrinkling is indicated by the circled area on the left.

**Fig. 43** Results of optimization of the initial virtual tryout based on the previous incremental analysis

usability. Once the technology is mature, simulations for the entire line-die operation described in previous sections will become common practice.

One of the most critical technology bottlenecks is the ability to model complex flanging and hemming over a tight radius. This will require a good material model with reliable parameters and advanced element formulation, among other things. Springback prediction after the final operation may become possible if the simulation can provide accurate and reliable stress distributions.

As the accuracy for springback prediction for line dies improves, die compensation for line dies besides the first draw die will become popular. The distortion induced by the flanging operation can possibly be minimized then. This may also spark interest for overall springback correction, because it may not be the optimal solution to minimize springback after each operation using die-compensation methodology.

*Other Simulation Features Supporting the Line Dies.* New hardware, such as the crossbar transfer press, has been created to accelerate production. This new hardware has modified the production process itself, which may create secondary problems. Some details either being omitted or simplified in current practices will be added to future CAE models for better accuracy. Examples may include the following:

- Gaging of the blank
- Actual bead geometry
- Actual trimming with solid elements
- Actual nitrogen (or air) pins instead of overall binder force
- More accurate weld-line modeling for tailor-welded blank applications
- Transferring of the sheet metal between dies
- Die flex and die wear consideration
- Scrap cutting and removal

*Assembly Simulations with Formed Parts.* Subassembly or vehicle assembly with "relaxed" parts (i.e., after springback) will become a popular issue. Currently, most assembly simulations rely on measurement data. This is often too late to make a big impact. If the total springback prediction is reliable, then the assembly simulation can be done much earlier in the program, without any hardware.

Another example of a new requirement for simulation can be seen from the evolution in welding technology. Whereas traditional spot welding integrated the weld and clamp and allowed for standard tolerances, the increased use of laser welding requires a more sophisticated clamping system and a very low flange tolerance. This technology has a large impact indeed on tolerance control, which translates to springback problems on the part at the forming stage. This evolution in process again illustrates the need for increased precision and tighter control during stamping simulation.

*Alternative Forming Simulation and Innovative Manufacturing Simulation.* Many non-

traditional forming methods have been adopted in the last decade. Some can be handled fairly well with the current simulation technology. These include tube hydroforming, fluid forming (sheet hydroforming), tailored-welded blanks, superplastic forming, and warm forming. Because the business case for those methods is not as strong as for traditional stamping, the push for technology growth in these areas has not been as strong. There is room for improvement for these simulations, such as automatic pressure regulation for hydroforming. Business demands will dictate the future growth.

Other innovative simulations may include the need for surface-quality evaluation, process optimization, optimal metal flow control, process layout, automatic die-face development, and so on. Some of the calculations are very CPU-intensive; hence, the cost reduction and the growth of the MPP technology will have a strong impact on the feasibility of the aforementioned simulations. Future studies, with the help of better CAE technology, are also required to reduce the number of parts through part consolidation.

*Technology Collaboration.* Forming simulation in its earlier iterations has become inadequate. The focus has shifted from the initial objective for formability analysis to much broader applications, quality improvement, cost reduction, and integration. Forming simulations need to adapt to these new requirements. The most important among these are:

- Providing a streamlined, scalable environment that encompasses every step in the process, from early feasibility to final validation
- Increased precision through model parameterization to assess new materials and their properties, to accurately predict springback behavior and surface-quality problems
- Seamless simulation data transfer and management to keep track of part history at every stage in the process, in order to check the performance and the robustness of the product and its consistency as well
- Optimal exploitation of available computer resources in a customizable, extended, collaborative environment

It is not feasible for any manufacturing or CAE software company to work alone to meet future demands. More collaboration among the academia, CAE software developers, materials suppliers, and users is needed.

## ACKNOWLEDGMENTS

Sheet metal forming simulation has made tremendous progress. Technology advancements have come from the academic field; researchers and users in automotive, appliance, steel, aluminum, aerospace, and other industries; developers from the software companies; and expert consultants. They should all be recognized for their contributions. Many of their names are listed in the reference section.

In particular, Fouad El Khaldi of the ESI Group, Arthur Tang and C.C. Chen of ETA, Dr. Xinahi Zhu of LSTC, and Dr. Kidambi S. Kannan of AutoForm Engineering provided valuable material and generously supplied many graphics. Thanks are due to Wei-Tsu Wu of Scientific Forming Technologies Corporation for his guidance, support, and encouragement. The author would also like to express his sincere thanks to Daniel Sa for his great effort in editing the draft manuscript, and to the ASM International staff for their support, coordination, and enhancement of the manuscript.

# Modeling and Simulation of the Forming of Aluminum Sheet Alloys

Jeong Whan Yoon and Frédéric Barlat, Alloy Technology and Materials Research Division, Alcoa Technical Center

WITH ADVANCES in computer hardware and software, it is possible to model material processing, product manufacturing, product performance in service, and failure. Although the fine-tuning of product manufacturing and performance is empirical, modeling can be an efficient tool to guide and optimize design, to evaluate material attributes, and to predict life-time and failure. Moreover, modeling can be used as a research tool for a more fundamental understanding of physical phenomena that can result in the development of improved or new products.

This article is concerned with the numerical simulation of the forming of aluminum alloy sheet metals. In order to design a process for a specific material, it is necessary to account for the attributes of the material in the simulations. Although the numerical methods are generic and can be applied to any material, constitutive models, that is, the mathematical descriptions of material behavior, are material-specific. Therefore, macroscopic and microscopic aspects of the plastic behavior of aluminum alloys are reviewed first. The following are then discussed to cover theoretical and implementation aspects of sheet metal forming simulation:

- Constitutive equations suitable for the description of aluminum alloy sheets
- Testing procedures and analysis methods used to measure the relevant data needed to identify the material coefficients
- Tensile and compressive instabilities in sheet forming. For tensile instability, both strain- and stress-based forming-limit curves are discussed.
- Springback analysis
- Finite Element (FE) formulation
- Stress-integration procedures for both continuum and crystal-plasticity mechanics
- Finite element design

Finally, various examples of the simulation of aluminum sheet forming are presented. These examples include earing in cup drawing, wrinkling, automotive stamping, hemming, hydroforming, and clam-shell-resistant design via

FE analysis and the Taguchi (Ref 1) optimization method.

## Material Modeling

### *Plasticity of Aluminum Alloys*

**Macroscopic Observations.** Aspects of the plastic deformation and ductility of aluminum alloys at low and moderate strain rates and subjected to monotonic loading or to a few load cycles are briefly discussed here. The stress-strain behavior at low strain is almost always reversible and linear. The elastic range, however, is bounded by the yield limit, the stress above which permanent or inelastic deformations occur. In the plastic range, the flow stress, described by a stress-strain curve, increases with the amount of accumulated plastic strain and becomes the new yield stress if the material is unloaded.

In general, it is considered that plastic deformation occurs without any volume change and that hydrostatic pressure has no influence on yielding. Experiments conducted at high confinement pressure showed that, although very small, a pressure effect is quantifiable (Ref 2, 3). However, practically, this effect can be neglected for aluminum alloys at low confinement pressure. A feature common in aluminum alloys is the Bauschinger effect. This occurs when a material is deformed up to a given strain, unloaded, and loaded in the reverse direction—typically, tension followed by compression. The yield stress after strain reversal is lower than the flow stress before unloading from the first deformation step.

The flow stress of an alloy depends on the testing temperature. Moreover, at low absolute temperature compared to the melting point, time usually has a very small influence on the flow stress and plasticity in general. However, at higher temperatures, strain-rate effects are important. In fact, it has been observed that strain rate and temperature have virtually identical effects on plasticity. Raising the temperature

under which an experiment is carried out is similar to decreasing the strain rate. Temperature has another influence on plasticity. When subjected to a constant stress smaller than the yield limit, a material can deform by creep. A similar phenomenon, called relaxation, corresponds to a decrease in the applied stress when the strain is held constant.

**Microscopic Aspects.** Commercial aluminum alloys used in forming operations are polycrystalline. They are composed of numerous grains, each with a given lattice orientation with respect to macroscopic axes. At low temperature compared to the melting point, metals and alloys deform by dislocation glide or slip on given crystallographic planes and directions, which produces microscopic shear deformations (Ref 4). Therefore, the distribution of grain orientations—the crystallographic texture—plays an important role in plasticity. Because of the geometrical nature of slip deformation, strain incompatibilities arise between grains and produce micro-residual stresses, which macroscopically lead to a Bauschinger effect. Slip results in a gradual lattice rotation as deformation proceeds. After slip, dislocations accumulate at microstructural obstacles and increase the slip resistance for further deformation, leading to strain hardening with its characteristic stress-strain curve.

At higher temperature, more slip systems can be available to accommodate the deformation (Ref 5), but grain-boundary sliding becomes more predominant. For instance, superplastic forming occurs mainly by grain-boundary sliding (Ref 6). In this case, the grain size and shape are important parameters. Atomic diffusion is also another mechanism that affects plastic deformation at high temperature and contributes to creep as well as the accommodation of stress concentrations that arise due to grain-boundary sliding.

Commercial aluminum alloys contain second-phase particles. These phases are present in materials by design in order to control either the microstructure, such as the grain size, or mechanical properties, such as strength (Ref 7, 8).

However, some amounts of second phases are undesired. In any case, the presence of these nonhomogeneities alters the material behavior because of their differences in elastic properties with the matrix, such as in composite materials, or because of their interactions with dislocations. In both cases, these effects produce incompatibility stresses that lead to a Bauschinger effect.

The mechanisms of failure intrinsic to materials are flow localization and fracture. Localization tends to occur in the form of shear bands, either microbands, which tend to be crystallographic, or macrobands, which are not (Ref 9). Macroscopic necking in thin sheet occurs under either three-dimensional conditions (e.g., diffuse necking) or plane-strain conditions (e.g., localized, through-thickness necking). Ductile fracture is generally the result of a mechanism of void nucleation, growth, and coalescence (Ref 10). The associated microporosity leads to volume changes, although the matrix is plastically incompressible, and hydrostatic pressure affects the material behavior. At low temperature compared to the melting point, second phases are principally the sites of damage. The stress concentration around these phases leads to void nucleation, and growth occurs by plasticity. Coalescence is the result of plastic flow micro-localization of the ligaments between voids. At higher temperature, where creep becomes dominant, cavities nucleate at grain boundaries by various mechanisms, including grain sliding and vacancy coalescence. Generally, materials subjected to creep and superplastic forming exhibit higher porosity levels than those formed at lower temperature.

## Constitutive Behavior

**General Approach.** Constitutive laws in materials generally consist of a state equation and evolution equations. The state equation describes the relationship between the strain rate ( $\dot{\epsilon}$ ), stress ( $\sigma$ ), temperature ( $T$ ), and state variables ( $x^k$ ), which represent the microstructural state of the material (Ref 11). The porosity of a material and a measure of the accumulated plastic deformation, such as the effective strain or the dislocation density, are a few examples of the variables  $x^k$ . The state equation can be expressed mathematically, for instance, in a scalar form for uniaxial deformation, as:

$$\dot{\epsilon} = \dot{\epsilon}(\sigma, T, x^k) \quad (\text{Eq 1})$$

The evolution equations describe the development of the microstructure through the change of the state variables and can take the form:

$$\dot{x}^k = \dot{x}^k(\sigma, T, x^k) \quad (\text{Eq 2})$$

Because slip plays a major role in plasticity, it is important to look at this mechanism in terms of both its kinetic effect on strain hardening and its geometrical effect on anisotropy. The Kocks and Mecking approach (Ref 12)

has laid the foundations for many subsequent studies by connecting the dislocation density to the flow stress. With this type of approach, it is possible to model the influence of parameters describing the microstructure, such as grain size, second phases, and solutes. Other approaches to strain hardening include dislocation dynamics and atomistic computation. However, these methods are very computationally intensive at this time and not appropriate for forming simulations.

The description of crystal plasticity has been very successful over the last few decades. This approach is based on the geometrical aspect of plastic deformation, slip and twinning in crystals, and on averaging procedures over a large number of grains. The crystallographic texture is the main input to these models, but other parameters, such as the grain shape, can also be included. It is a multiaxial approach and involves tensors instead of scalar variables. One of the outputs of a polycrystal model is the concept of the yield surface, which generalizes the concept of uniaxial yield stress for a multiaxial stress state. Polycrystal models can be used in multi-scale simulations of forming, but they are usually expensive in time, and the relevant question is to know if their benefit is worth the cost. Polycrystal modeling aspects have been treated in a large number of publications and books, such as in Ref 4, 13, and 14.

The state variables do not need to be connected to a specific microstructural feature. In this case, Eq 1 and 2 define a macroscopic model with state (or internal) variables. In fact, for forming applications, macroscopic models appear to be more appropriate. Because of the scale difference between the microstructure and a stamped part, the amount of microscopic material information necessary to store in a forming simulation would be excessively large. It is not possible to track all of the relevant microstructural features in detail. Therefore, lumping them all in a few macroscopic variables seems to be more appropriate and efficient.

**Constitutive Modeling for Aluminum Alloys.** At the continuum scale, for a multiaxial stress space, plastic deformation is well described with a yield surface, a flow rule, and a hardening law. The yield surface in stress space separates states producing elastic and elastoplastic deformation. It is a generalization of the tensile yielding behavior to multiaxial stress states. Plastic anisotropy is the result of the distortion of the yield surface shape due to the material microstructural state. Reference 15 discusses different phenomena attached to the yield surface shape at a macroscopic scale.

Certain properties of the continuum yield functions can be obtained from microstructural considerations. Bishop and Hill (Ref 16) showed that for a single crystal obeying the Schmid law (i.e., dislocation glide occurs when the resolved shear stress on a slip system reaches a critical value), the resulting yield surface is convex, and

the associated strain increment is normal to it. Furthermore, they extended this result to a polycrystal by averaging the behavior of a representative number of grains in an elementary volume without making any assumption about the interaction modes between grains or the uniformity of the deformation gradient. These results provide a good support for the use of the associated flow rule, which stipulates that the strain rate (increment) is normal to the yield surface.

Regardless of the shape of the yield surface, strain hardening can be isotropic or anisotropic. The former corresponds to an expansion of the yield surface without distortion. Any other form of hardening is anisotropic and leads to different properties in different directions after deformation, even if the material is initially isotropic. Whether the yield surface expands, translates, or rotates as plastic deformation proceeds, a shape must be defined to account for initial anisotropy.

If the yield surface distorts during deformation, a unique shape can still be used to describe an average material response over a certain deformation range (Ref 17). Because mechanical data are used as input, these models can still be relatively accurate when the strain is moderate. This is typically the case for sheet forming. However, for larger strains and for abrupt strain path changes, evolution is an issue (for instance, see Ref 18 to 26). Nevertheless, the description of plastic anisotropy based on the concept of yield surfaces and isotropic hardening is convenient and time-efficient for engineering applications such as forming-process simulations. Moreover, the translation of a yield surface (kinematic hardening), which captures phenomena such as the Bauschinger effect, can be easily integrated in an FE formulation.

In view of the previous section, it is obvious that it is difficult to develop constitutive models for forming applications that capture all the macroscopic and microscopic phenomena involved in plastic deformation and ductile fracture. Therefore, the discussion is mostly restricted to behavior where isotropic hardening is a good approximation. Practically, this approach is robust and reasonably accurate in many situations. In classical plasticity, the material description is fully defined using the following set of equations:

$$\Phi(\sigma_{ij}) = \bar{\sigma} \quad (\text{yield function/effective stress}) \quad (\text{Eq 3})$$

$$\bar{\sigma} = h(\bar{\epsilon}) \quad (\text{yield condition}) \quad (\text{Eq 4})$$

$$\dot{\epsilon}_{ij} = \dot{\lambda} \frac{\partial \Phi}{\partial \sigma_{ij}} \quad (\text{associated or normality flow rule}) \quad (\text{Eq 5})$$

where  $\sigma_{ij}$  and  $\dot{\epsilon}_{ij}$  are the stress and strain-rate tensor components, and  $\dot{\lambda}$  is a proportionality factor. The overdot indicates the derivative with respect to time. The variable  $h$  is the strain-hardening law (function), which expands the

yield surface as plastic deformation accumulates. The symbol  $\bar{\sigma}$  is the effective stress, and  $\bar{\epsilon}$  is the work-equivalent effective strain defined incrementally as:

$$\bar{\sigma} \dot{\bar{\epsilon}} = \sum_{i,j} \sigma_{ij} \dot{\epsilon}_{ij} = \sigma_{ij} \dot{\epsilon}_{ij} \quad (\text{Eq 6})$$

The last expression is an abbreviation of the summation using the Einstein convention. Any repeated index indicates the summation of a product over 1 to 3. Note that this formulation (Eq 3 to 6) is consistent with the general framework defined by Eq 1 and 2. The problem reduces to the definitions of the hardening law and yield function,  $h$  and  $\bar{\sigma}$  (or  $\Phi$ ), respectively.

The Swift power law (Ref 27), a very popular approximation of the hardening function  $h$ , is defined as:

$$h(\bar{\epsilon}) = K(\epsilon_0 + \bar{\epsilon})^n \quad (\text{Eq 7})$$

where  $K$  and  $n$  are the strength coefficient and strain-hardening exponent, respectively. The symbol  $\epsilon_0$  is another coefficient that, if equal to zero, reduces Eq 7 to the Hollomon (Ref 28) hardening law. However, one of the outcomes of the dislocation-based Kocks and Mecking approach mentioned previously is that, macroscopically, the strain-hardening behavior for aluminum alloys can be better described with the Voce law (Ref 29):

$$h(\bar{\epsilon}) = A - B \exp(-C\bar{\epsilon}) \quad (\text{Eq 8})$$

where  $A$ ,  $B$ , and  $C$  are constant coefficients. Therefore, this equation is often preferred to represent the hardening behavior of aluminum alloys, although, as discussed in the section "Test Data Analysis" in this article, is necessary to understand the consequences of the fitting procedure on the modeled material response. It can be assumed that the effects of temperature and strain rate can be included in the formulation through  $h$ , for instance, using  $h = h(\bar{\epsilon}, \dot{\bar{\epsilon}}, T)$ . As an example, a practical way to include strain-rate effects is to separate this variable from strain hardening through the use of the strain-rate sensitivity parameter  $m$ :

$$h = g(\bar{\epsilon}) \left( \frac{\dot{\bar{\epsilon}}}{\dot{\bar{\epsilon}}_r} \right)^m \quad (\text{Eq 9})$$

where  $g$  is the strain-hardening law at the reference strain rate  $\dot{\bar{\epsilon}}_r$ , and  $m$  is the strain-rate sensitivity parameter defined as:

$$m = \frac{\partial \ln(\sigma)}{\partial \ln(\dot{\epsilon})} \bigg|_{\epsilon} \quad (\text{Eq 10})$$

It is worthy to note that the strain-rate sensitivity parameter  $m$  is very close to zero for most aluminum alloys at room temperature. However,  $m$  can be slightly higher at low temperature and relatively large at higher temperature (Ref 30), particularly for conditions of superplastic deformation (Ref 6).

For cubic metals, there are usually enough potentially active slip systems to accommodate

any shape change imposed to the material. Compressive and tensile yield strengths are virtually identical, and yielding is not influenced by the hydrostatic pressure. The yield surface of such materials is usually represented adequately by an even function of the principal values  $S_k$  of the stress deviator  $\mathbf{s}$ , such as proposed by Hershey (Ref 31) and Hosford (Ref 32), that is:

$$\phi = |S_1 - S_2|^a + |S_2 - S_3|^a + |S_3 - S_1|^a = 2\bar{\sigma}^a \quad (\text{Eq 11})$$

With respect to the stress tensor components  $\sigma_k$ , the deviatoric stresses  $S_k$  are given by:

$$S_k = \sigma_k - (\sigma_1 + \sigma_2 + \sigma_3)/3 \quad (\text{Eq 12})$$

The yield function in Eq 11 can be framed into the general form of Eq 3, using the simple transformation  $\Phi = (\phi/2)^{1/a}$ . The exponent "a" is related to the crystal structure of the lattice, that is, 6 for body-centered cubic (bcc) and 8 for face-centered cubic (fcc) materials (Ref 33, 34). This was established as a result of many polycrystal simulations. Therefore, although this model is macroscopic, it contains some information pertaining to the structure of the material.

For the description of incompressible plastic anisotropy, many yield functions have been suggested based on the isotropic-hardening assumption (Ref 35–39). Among them, Cazacu and Barlat (Ref 39) introduced a general formulation that originated from the rigorous theory of representation of tensor functions. However, with this approach, the conditions for the convexity of the yield surface are difficult to impose. As mentioned previously in this section, the convexity has a physical basis, and, in addition, this property ensures numerical stability in computer simulations. For this reason, a particular case of this general theory, which is based on linearly transformed stress components, has received more attention. Barlat et al. (Ref 37) applied this method to a general stress state in an orthotropic material, and Karafillis and Boyce (Ref 38) generalized it as the so-called isotropic plasticity equivalent theory, with a more general yield function and a linear transformation that can accommodate lower material symmetry. Cazacu et al. (Ref 40) proposed a criterion based on a linear transformation that accounts for the strength-differential effect, particularly prominent in hexagonal close-packed metals.

Because the aforementioned functions are not able to capture the anisotropic behavior of aluminum sheet to a desirable degree of accuracy, Barlat et al. (Ref 41, 42) introduced two linear transformations operating on the sum of two yield functions in the case of plane stress and general stress states, respectively. Bron and Besson (Ref 43) further extended Karafillis and Boyce's approach to two linear transformations. These recently proposed yield functions include more anisotropy coefficients and therefore give a better description of the anisotropic properties of a material. This is particularly obvious for

the description of uniaxial tension properties (Ref 42).

Extensions of Eq 11 to planar anisotropy for plane stress and general stress states are briefly summarized in the section "Anisotropic Yield Functions" in this article. Both formulations are based on two linear transformations of the stress deviator. The two linear transformations can be expressed as:

$$\begin{aligned} \tilde{\mathbf{s}}' &= \mathbf{C}' \mathbf{s} = \mathbf{C}' \mathbf{T} \boldsymbol{\sigma} = \mathbf{L}' \boldsymbol{\sigma} \\ \tilde{\mathbf{s}}'' &= \mathbf{C}'' \mathbf{s} = \mathbf{C}'' \mathbf{T} \boldsymbol{\sigma} = \mathbf{L}'' \boldsymbol{\sigma} \end{aligned} \quad (\text{Eq 13})$$

where  $\mathbf{T}$  is a matrix that transforms the Cauchy stress tensor  $\boldsymbol{\sigma}$  to its deviator  $\mathbf{s}$ :

$$\mathbf{T} = \frac{1}{3} \begin{bmatrix} 2 & -1 & -1 & 0 & 0 & 0 \\ -1 & 2 & -1 & 0 & 0 & 0 \\ -1 & -1 & 2 & 0 & 0 & 0 \\ 0 & 0 & 0 & 3 & 0 & 0 \\ 0 & 0 & 0 & 0 & 3 & 0 \\ 0 & 0 & 0 & 0 & 0 & 3 \end{bmatrix} \quad (\text{Eq 14})$$

In Eq 13,  $\tilde{\mathbf{s}}'$  and  $\tilde{\mathbf{s}}''$  are the linearly transformed stress deviators, while  $\mathbf{C}'$  and  $\mathbf{C}''$  (or  $\mathbf{L}'$  and  $\mathbf{L}''$ ) are the matrices containing the anisotropy coefficients. Specific forms of these matrices are given subsequently for materials exhibiting the orthotropic symmetry, that is, with three mutually orthogonal planes of symmetry at each point of the continuum, such as in sheet metals or tubes. The unit vectors describing the symmetry axes are denoted by  $\mathbf{x}$ ,  $\mathbf{y}$ , and  $\mathbf{z}$ , which, for sheet materials, correspond to the rolling, transverse, and normal directions, respectively.

**Anisotropic Yield Functions.** For plane stress, these two linear transformations can be defined as:

$$\begin{aligned} \begin{bmatrix} \tilde{s}'_{xx} \\ \tilde{s}'_{yy} \\ \tilde{s}'_{xy} \end{bmatrix} &= \begin{bmatrix} \alpha_1 & 0 & 0 \\ 0 & \alpha_2 & 0 \\ 0 & 0 & \alpha_7 \end{bmatrix} \begin{bmatrix} s_{xx} \\ s_{yy} \\ s_{xy} \end{bmatrix} \\ \begin{bmatrix} \tilde{s}''_{xx} \\ \tilde{s}''_{yy} \\ \tilde{s}''_{xy} \end{bmatrix} &= \frac{1}{3} \begin{bmatrix} 4\alpha_5 - \alpha_3 & 2\alpha_6 - 2\alpha_4 & 0 \\ 2\alpha_3 - 2\alpha_5 & 4\alpha_4 - \alpha_6 & 0 \\ 0 & 0 & 3\alpha_8 \end{bmatrix} \\ &\quad \times \begin{bmatrix} s_{xx} \\ s_{yy} \\ s_{xy} \end{bmatrix} \end{aligned} \quad (\text{Eq 15})$$

By denoting  $\tilde{S}'_i$  and  $\tilde{S}''_j$  the principal values of the tensors  $\tilde{\mathbf{s}}'$  and  $\tilde{\mathbf{s}}''$  defined previously, the plane-stress anisotropic yield function Yld2000-2d is then defined as:

$$\phi = |\tilde{S}'_1 - \tilde{S}'_2|^a + |\tilde{S}''_2 - \tilde{S}''_1|^a + |\tilde{S}''_1 + \tilde{S}'_2|^a = 2\bar{\sigma}^a \quad (\text{Eq 16})$$

Note that this formulation is isotropic and reduces to Eq 11 if  $\mathbf{C}'$  and  $\mathbf{C}''$  are both equal to the identity matrix. It also reduces to the classical von Mises and Tresca yield functions if  $a = 2$  (or 4) and  $a = 1$  (or  $\infty$ ), respectively. More

details regarding Yld2000-2d are given in Ref 41 and 44.

For a full three-dimensional stress state, the linear transformations can be expressed in the most general form with the following matrices:

$$\mathbf{C}' = \begin{bmatrix} 0 & -c'_{12} & -c'_{13} & 0 & 0 & 0 \\ -c'_{21} & 0 & -c'_{23} & 0 & 0 & 0 \\ -c'_{31} & -c'_{32} & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & c'_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & c'_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & c'_{66} \end{bmatrix};$$

$$\mathbf{C}'' = \begin{bmatrix} 0 & -c''_{12} & -c''_{13} & 0 & 0 & 0 \\ -c''_{21} & 0 & -c''_{23} & 0 & 0 & 0 \\ -c''_{31} & -c''_{32} & 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & c''_{44} & 0 & 0 \\ 0 & 0 & 0 & 0 & c''_{55} & 0 \\ 0 & 0 & 0 & 0 & 0 & c''_{66} \end{bmatrix} \quad (\text{Eq 17})$$

The anisotropic yield function Yld2004-18p is defined as:

$$\begin{aligned} \phi = \phi(\tilde{S}'_i, \tilde{S}''_j) = & |\tilde{S}'_1 - \tilde{S}''_1|^a + |\tilde{S}'_1 - \tilde{S}''_2|^a \\ & + |\tilde{S}'_1 - \tilde{S}''_3|^a + |\tilde{S}'_2 - \tilde{S}''_1|^a + |\tilde{S}'_2 - \tilde{S}''_2|^a \\ & + |\tilde{S}'_2 - \tilde{S}''_3|^a + |\tilde{S}'_3 - \tilde{S}''_1|^a + |\tilde{S}'_3 - \tilde{S}''_2|^a \\ & + |\tilde{S}'_3 - \tilde{S}''_3|^a = 4\bar{\sigma}^a \end{aligned} \quad (\text{Eq 18})$$

This formulation is isotropic if all the coefficients  $c'_{ij}$  and  $c''_{ij}$  reduce to unity. The reader is referred to Ref 42 for additional information about this model.

**Strain-Rate Potentials.** In order to represent the rate-insensitive plastic behavior of materials phenomenologically, it is typical, as explained previously, to use a yield surface, the associated flow rule, and a hardening law. Ziegler (Ref 45) and Hill (Ref 46) have shown that, based on the work-equivalence principle, Eq 6, a meaningful strain-rate potential can be associated to any convex stress potential (yield surface). Therefore, an alternate approach to describe plastic anisotropy is to provide a strain-rate potential  $\Psi(\dot{\boldsymbol{\epsilon}}) = \bar{\epsilon}$ , expressed as a function of the traceless plastic strain-rate tensor  $\dot{\boldsymbol{\epsilon}}$ , the gradient of which leads to the direction of the stress deviator  $\mathbf{s}$ , that is:

$$s_{ij} = \mu \frac{\partial \Psi}{\partial \dot{\epsilon}_{ij}} \quad (\text{Eq 19})$$

In the previous equation,  $\mu$  is a proportionality factor necessary to scale the stress deviator. Note the similarity between Eq 19 and Eq 5. This approach has been used for the description of the plastic behavior of fcc single crystals (Ref 47), bcc polycrystals (Ref 48–50), and cubic polycrystals (Ref 51–52). In the latter works,

the strain-rate potential  $\Psi = (\psi/k)^{1/b}$  for an incompressible isotropic material was defined using:

$$\begin{aligned} \psi = & \left| \frac{2\dot{E}_1 - \dot{E}_2 - \dot{E}_3}{3} \right|^b + \left| \frac{2\dot{E}_2 - \dot{E}_3 - \dot{E}_1}{3} \right|^b \\ & + \left| \frac{2\dot{E}_3 - \dot{E}_1 - \dot{E}_2}{3} \right|^b = |\dot{E}_1|^b + |\dot{E}_2|^b + |\dot{E}_3|^b \\ = & k\dot{\bar{\epsilon}}^b \end{aligned} \quad (\text{Eq 20})$$

where  $\dot{E}_i$  represents the principal values of the plastic strain-rate tensor  $\dot{\boldsymbol{\epsilon}}$ , and  $\dot{\bar{\epsilon}}$  is the effective strain rate defined using the plastic work equivalence principle with the effective stress  $\bar{\sigma}$  (Eq 6). The constant  $k$  defines the size of the potential, and the exponent “ $b$ ” was shown to be  $3/2$  and  $4/3$  for an optimal representation of bcc and fcc materials, respectively. For orthotropic materials, the principal values  $\dot{E}_i$  of a linearly transformed plastic strain rate tensor  $\dot{\boldsymbol{\epsilon}}$ , that is:

$$\dot{\boldsymbol{\epsilon}} = \mathbf{B}\dot{\boldsymbol{\epsilon}} \quad (\text{Eq 21})$$

where  $\mathbf{B}$  is the matrix containing six anisotropy coefficients, are substituted for  $\dot{E}_1$  in Eq 20. This formulation reduces to isotropy when  $\mathbf{B}$  becomes the identity matrix (i.e.,  $\dot{\boldsymbol{\epsilon}} = \dot{\boldsymbol{\epsilon}}$ ). However, it is generally accepted that six coefficients are not sufficient to describe the plastic behavior of anisotropic aluminum alloy sheets very accurately. Therefore, a formulation that accounts for two linear transformations on the traceless plastic strain-rate tensor  $\dot{\boldsymbol{\epsilon}}$  was recently introduced:

$$\dot{\boldsymbol{\epsilon}}' = \mathbf{B}'\dot{\boldsymbol{\epsilon}} = \mathbf{B}'\mathbf{T}\dot{\boldsymbol{\epsilon}} \quad (\text{Eq 22})$$

$$\dot{\boldsymbol{\epsilon}}'' = \mathbf{B}''\dot{\boldsymbol{\epsilon}} = \mathbf{B}''\mathbf{T}\dot{\boldsymbol{\epsilon}} \quad (\text{Eq 23})$$

where  $\dot{\boldsymbol{\epsilon}} = \mathbf{T}\dot{\boldsymbol{\epsilon}}$  is another expression of the traceless plastic strain-rate tensor, necessary to ensure that the strain-rate potential is a cylinder through the transformation represented by  $\mathbf{T}$  defined previously. The specific strain-rate potential, called Spr2004-18p, was postulated (Ref 53):

$$\begin{aligned} \psi = \psi(\tilde{E}'_i, \tilde{E}''_j) = & |\tilde{E}'_1|^b + |\tilde{E}'_2|^b + |\tilde{E}'_3|^b \\ & + |\tilde{E}''_2 + \tilde{E}''_3|^b + |\tilde{E}''_3 + \tilde{E}''_1|^b + |\tilde{E}''_1 + \tilde{E}''_2|^b \\ = & (2^{2-b} + 2)\dot{\bar{\epsilon}}^b \end{aligned} \quad (\text{Eq 24})$$

where  $\tilde{E}'_i$  and  $\tilde{E}''_j$  are the principal values of the tensors  $\dot{\boldsymbol{\epsilon}}'$  and  $\dot{\boldsymbol{\epsilon}}''$ . Here, the anisotropy coefficients are contained in matrices  $\mathbf{B}'$  and  $\mathbf{B}''$ , both of a form similar to  $\mathbf{C}'$  and  $\mathbf{C}''$  in Eq 17.

## Experiments and Constitutive Parameters

**Testing Methods.** Multiaxial experiments have been used to characterize a yield surface, and many issues have been addressed (Ref 54,

55). Recently, Banabic et al. (Ref 56) improved a procedure for biaxial testing of cruciform specimens machined from thin sheets, and for measuring the first quadrant of the yield locus (both stresses positive). In these tests, the onset of plastic deformation is detected from temperature measurements of specimens using an infrared thermocouple positioned at an optimized distance. This method is based on the fact that the specimen temperature drops first due to thermoelastic cooling and then rises significantly when dissipative plastic flow initiates. In spite of this and other types of improvements, multiaxial testing is tedious, difficult to conduct and interpret, and not suitable for quick characterization of anisotropy. This is more a technique for careful verifications of concepts and theories. Therefore, more practical and time-efficient methods are required to test materials and identify material coefficients in constitutive equations, in particular for sheets.

Anisotropic properties can be assessed by performing uniaxial tension tests in the  $\mathbf{x}$  and  $\mathbf{y}$  axes (rolling and transverse directions, respectively) and in a direction at  $\theta$  degrees with respect to  $\mathbf{x}$ . Practically, the anisotropy is characterized by the yield stresses  $\sigma_0$ ,  $\sigma_{45}$ ,  $\sigma_{90}$ ; the  $r$ -values (width-to-thickness strain ratio in uniaxial tension)  $r_0$ ,  $r_{45}$ ,  $r_{90}$ ; and their respective averages  $\bar{q} = (q_0 + 2q_{45} + q_{90})/4$  and variations  $\Delta\bar{q} = (q_0 - 2q_{45} + q_{90})/2$ . For a better characterization of anisotropy, tensile specimens are cut from a sheet at angles of 0, 15, 30, 45, 60, 75, and 90° from the rolling direction. Tension tests are usually conducted at room temperature (RT), and standard (ASTM International) methods are used to measure the yield stresses and  $r$ -values. For some aluminum alloys, however, the stress-strain curve exhibits serrations, resulting from nonhomogeneous deformation of the tensile specimen. For instance, Fig. 1 shows the engineering tensile stress-strain curves measured in the 0, 45, and 90° directions at RT for a 5019A-O sheet sample. Because this phenomenon is due to inhomogeneous plastic deformation, the plastic strains measured with extensometers are not reliable and can lead to erroneous  $r$ -values. In order to overcome this problem, tension tests can be conducted at a somewhat higher temperature, where serrated flow is suppressed. For instance, Fig. 1 shows the engineering stress/engineering strain curves in the 0, 45, and 90° tension directions measured at RT and at a temperature of 93 °C (200 °F) for a 5019A-H48 sheet sample (Ref 57).

The balanced biaxial yield stress ( $\sigma_b$ ) is an important parameter to measure for sheet material characterization. This stress can be obtained by conducting a hydraulic bulge test (Ref 58). Figure 2 shows a schematic diagram of this test in which a sheet blank is clamped between a die with a large circular opening and a holder. A pressure,  $p$ , is gradually applied under the blank, which bulges in a quasi-spherical shape. The radius of curvature,  $R$ , and strains at the pole of

the specimen are measured independently, using mechanical or optical instruments. The stress  $\sigma = pR/2t$  is simply obtained from the membrane theory using the thickness,  $t$ . This test is interesting not only because it gives information on the yield surface, but also because it allows measurements of the hardening behavior up to strains of approximately twice those achieved in uniaxial tension. This is because geometrical instabilities occur during uniaxial tension (see the section “Strain-Based Forming-Limit Curves” in this article). However, the yield point is not well defined in the bulge test because of the low curvature of the specimen in the initial stage of deformation. As for uniaxial tension, this test can be conducted at different strain rates in order to assess the strain-rate sensitivity parameter  $m$ .

Because the biaxial stress state in the bulge test is not exactly balanced, measures of the corresponding strain state may lead to substantial errors. This is because the yield locus curvature

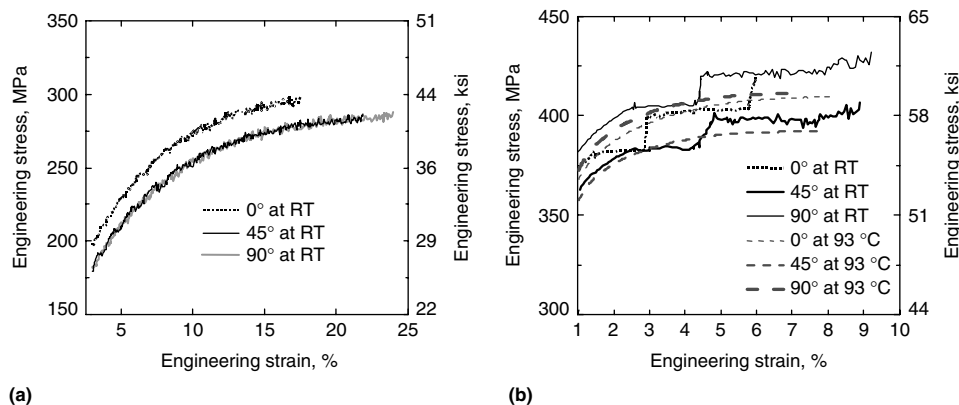

is usually high in this stress state. Barlat et al. (Ref 41) proposed the disk-compression test, which gives a measure of the flow anisotropy for a balanced biaxial stress state, assuming that hydrostatic pressure has no influence on plastic deformation. In this test, a 12.7 mm (0.5 in.) disk is compressed through the thickness direction of the sheet. The strains measured in the  $x$  and  $y$  directions lead to a linear relationship in which the slope is denoted by  $r_b$  by analogy to the  $r$ -value in uniaxial tension:

$$r_b = d\epsilon_{yy}^p / d\epsilon_{xx}^p \quad (\text{Eq 25})$$

This parameter is a direct measure of the slope of the yield locus at the balanced biaxial stress state. Figure 3 shows deformed specimens for 6111-T4 aluminum alloy sheet samples processed with two different routes, and the corresponding strain measures performed during this test. Pöhlndt et al. (Ref 59) proposed to determine the parameter  $r_b$  using the in-plane biaxial tension test.

Other tests can be used to characterize the material behavior of sheet samples. Directional tension of wide specimens can be used to characterize plane-strain tension anisotropy (Ref 60, 61). This test does not produce a uniform state of stress within the specimen and generally leads to more experimental scatter than the uniaxial test.

Simple shear tests (Ref 62) can be carried out to characterize the anisotropic behavior of the simple shear flow stress. A relatively simple device mounted on a standard tensile machine is needed for this test. A rectangular specimen is clamped with two grips, which move in opposite directions relative to each other (Fig. 4). By simply reversing the direction of the grip displacements, forward and reverse loading sequences can be conducted in order to measure the Bauschinger effect. In-plane tension-compression tests of thin sheets have also been used for this purpose (Ref 63, 64), but special precautions need to be taken because of the

buckling tendency of the specimen during the compressive step.

Although the previously described tests and other experimental procedures are available to test materials in different stress states, it is not always possible to probe all of them. In this case, microstructural modeling can be used to replace the missing experimental data. For instance, the resistance to through-the-thickness shear of a sheet,  $\sigma_s$ , is not readily available from experimental measurements. However, crystal plasticity with a measure of the crystallographic texture of the sheet can be used to compute  $\sigma_s$ . A rougher approximation is to assume that this value is equal to the isotropic shear stress, which, using Eq 11 and 12, for pure shear ( $\sigma_2 = -\sigma_1$ ,  $\sigma_3 = 0$ ) is equal to:

$$\frac{\sigma_s}{\bar{\sigma}} = \frac{1}{(2^{a-1} + 1)^{1/a}} \quad (\text{Eq 26})$$

**Test Data Analysis.** From the experimental tests, it is necessary to extract the right information that is most suitable for the identification of the constitutive parameters. For instance, the yield stresses can be used as input data to calculate the anisotropic yield function coefficients. However, as mentioned previously, the yield stress from the bulge test is not very accurate. Moreover, any stress at yield is determined in the region of the stress-strain curve where the slope is the steepest, which may involve additional inaccuracy. Finally, the yield stress is associated with a very small plastic strain and may not reflect the anisotropy of the material over a larger strain range. For these reasons, the flow stresses at equal amount of plastic work along different loading paths could be selected as input data instead of the yield stress. Figure 5 shows how the flow stresses in tension and balanced biaxial tension (bulge test) can be defined at equal amounts of plastic work ( $w_p = \int \sigma_{ij} \dot{\epsilon}_{ij} d\tau_{ij}$ , where  $\tau$  is the time). For many aluminum alloys, experimental observations show that after a few percent plastic strain, the flow stress anisotropy does not vary significantly, as illustrated by Fig. 6(a) and (b).

In the examples shown later in this article, the stress-strain curves employed in the forming simulations were measured using the bulge test, whenever possible. This test is important be-

cause extrapolation of uniaxial tension curves with the Voce law usually leads to an underestimation of strain hardening for strains higher than the limit of uniform elongation in tension. This is demonstrated in Fig. 6(c), which shows the Voce approximation of the bulge test data using two different strain ranges, that is, from zero up to strains of 0.2 and 0.53. These strain ranges are typical for uniaxial tension and balanced biaxial tension (bulge), respectively, for annealed aluminum alloys. This figure illustrates the risks of extrapolating flow stresses beyond the range of strains that was used for the fit. The stress-strain curve extrapolated

from the fit in the strain range 0–20% exhibits a much lower rate of strain hardening ( $d\sigma/d\epsilon$ ) after 25% deformation compared to the curve obtained experimentally with the bulge test.

Similar remarks hold for  $r$ -values, which can be defined as instantaneous quantities near yield or as the standard slope of the width strain/thickness strain curve over a given deformation range in tension. On one hand, the yield stresses and instantaneous  $r$ -values at yield seem to be appropriate to define the coefficients of the yield function. On the other hand, flow stresses defined at a given amount of plastic work and standard  $r$ -values can characterize the average behavior of the material over a finite deformation range. These values are more suitable and more descriptive of the average response of the material for sheet forming simulations. In this case, it would be more appropriate to talk about flow function and flow surface instead of yield function and yield surface, although, mathematically, yield or flow functions are identical concepts.

The anisotropy coefficients are calculated from flow stresses and  $r$ -values. For the yield function Yld2000-2d, the eight coefficients are computed numerically, using a Newton-Raphson numerical solver using eight input data: the flow stresses  $\sigma_0$ ,  $\sigma_{45}$ ,  $\sigma_{90}$ ,  $\sigma_b$  and the  $r$ -values  $r_0$ ,  $r_{45}$ ,  $r_{90}$ , and  $r_b$  (Ref 41). For the yield function Yld2004-18p, the 18 coefficients are computed numerically with an error-minimization method using 16 experimental input data: the flow stresses  $\sigma_0$ ,  $\sigma_{15}$ ,  $\sigma_{30}$ ,  $\sigma_{45}$ ,  $\sigma_{60}$ ,  $\sigma_{75}$ ,  $\sigma_{90}$ ,  $\sigma_b$  and the  $r$ -values  $r_0$ ,  $r_{15}$ ,  $r_{30}$ ,  $r_{45}$ ,  $r_{60}$ ,  $r_{75}$ ,  $r_{90}$ , and  $r_b$ . The remaining inputs, related to the through-thickness properties, are assumed to be equal to the isotropic values or are computed with a crystal-plasticity model (Ref 42). As an illustration of Yld2000-2d and Yld2004-18p, the predicted directionalities of the uniaxial flow stress and  $r$ -value for a 5019A-H48 aluminum alloy sheet sample are compared with experimental results in Fig. 7. This figure also shows that the yield function Yld91 (Ref 37), which uses only one linear transformation on the stress tensor, cannot properly capture the experimental variation of the  $r$ -value.

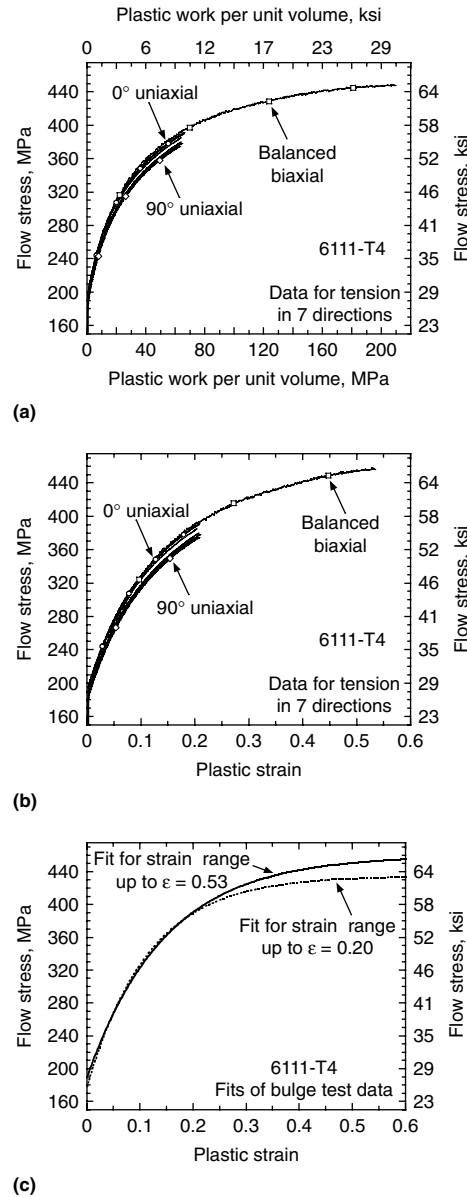

## Tensile Instability

The success of a sheet-forming operation can be limited by several phenomena, such as plastic flow localization, fracture, and buckling. For a given forming operation, the sheet may undergo deformation up to a given strain prior to failure by one of the limiting phenomena. In this section, analyses for plastic flow localization are discussed.

**Strain-Based Forming-Limit Curves.** The forming-limit curve (FLC) corresponds to the maximum admissible local strains achievable just before necking. This curve is usually plotted on axes representing the major ( $\epsilon_1$ ) and the minor ( $\epsilon_2$ ) strains in the plane of a sheet. Actually, for anisotropic materials, the major strain in the

**Fig. 5** Flow stresses at equivalent amount of plastic work in uniaxial tension,  $W_p^u$ , and balanced biaxial tension (bulge test),  $W_b^b$ , i.e., for  $W_p^u = W_b^b$

**Fig. 6** Flow stress as a function of (a) plastic work or (b) plastic strain for an aluminum alloy 6111-T4 sheet sample measured in balanced biaxial tension (bulge test) and uniaxial tension for directions at every 15° from the rolling direction. (c) Fit of Voce law to bulge-test data over two different strain ranges

rolling direction is different from the major strain in the transverse or in any other direction. Nevertheless, this convention is adopted in this section, although it lacks generality.

Different models have been proposed in the past to calculate the FLC. Swift (Ref 27) derived equations to predict diffuse necking. In real parts, however, the maximum admissible strains are typically limited by localized (through-thickness) necking, and Swift's equations have only limited applicability. The relationships giving the limit strain under local necking conditions were developed by Hill (Ref 65). His theory predicts that localized necking occurs in the characteristic directions of zero extension in the plane of the sheet. However, Hill's theory can only predict localized necking if one of the strains in the plane of the sheet is negative, that is, between uniaxial and plane-strain tension. This does not agree with experiments, because necking also occurs in stretching processes for which both in-plane principal strains are positive. To explain such behavior, Marciniak and Kuczynski (Ref 66) proposed an analysis in which the sheet metal is supposed to contain a region of local imperfection. Heterogeneous plastic flow develops and eventually localizes

in the imperfection. The Marciniak and Kuczynski (MK) model can predict the FLC when minor strains are either positive or negative. It was initially developed within the flow theory of plasticity, using quadratic plastic potentials. However, for balanced biaxial stretching ( $\varepsilon_2 = \varepsilon_1$ ) and within the classical plasticity approach ( $J_2$  flow theory), this model largely overestimates the limit strains. Therefore, Hutchinson and Neale (Ref 67) extended this model using the deformation theory of plasticity and were able to make predictions that were in better agreement with the experiments. Many other works have been published to show the influence of various parameters on calculated forming limits (for instance, Ref 68). Stören and Rice (Ref 69) gave another description of the plastic flow localization using a bifurcation analysis.

In the MK model, an infinite sheet metal is assumed to contain an imperfection, which is represented as a linear band of infinite size whose thickness  $t^l$  is smaller than the thickness of the homogeneous region of the sheet,  $t$ . The superscript "I" is used here for all the variables in the imperfection. Quantitatively, this two-zone material is characterized by parameter D:

$$D = 1 - t^l/t \quad (\text{Eq 27})$$

There is no imperfection when both thicknesses are identical, that is, when parameter D reduces to 0, and no plastic flow localization can be predicted with the MK model. However, if D has a starting value larger than zero, it will increase as plastic deformation proceeds. At each step of the calculation, the ratio of the effective strain rate in the homogeneous region ( $\dot{\varepsilon}$ ) to the effective strain rate in the imperfection ( $\dot{\varepsilon}^l$ ) is evaluated. Plastic flow localization occurs when this ratio approaches 0. The basic equations of the MK model are related to equilibrium and compatibility requirements. The first condition indicates that the force perpendicular to the necking band is transmitted from the homogeneous region to the imperfection, whereas, the second requirement indicates that the elongation in the direction of the necking band is identical in both regions. For materials exhibiting isotropy or planar isotropy (same properties in any direction in the plane of the sheet), the main equilibrium equation of the MK model reduces to the following form:

$$[1 - D] \left[ \frac{h(\bar{\varepsilon}^l)}{h(\bar{\varepsilon})} \right] \left[ \frac{\bar{\sigma}_1^l}{\bar{\sigma}_1} \right] = 1 \quad (\text{Eq 28})$$

where  $h(\bar{\varepsilon})$  is the hardening law, and  $\bar{\sigma}_1 = \sigma_1/\bar{\sigma}$  is the maximum principal stress normalized by the effective stress.

The MK model also suggests the necking direction per se. In the negative  $\rho$  range ( $\rho = d\varepsilon_2/d\varepsilon_1 \leq 0$ ) lying between uniaxial tension and plane-strain tension, the necking direction is at an angle with respect to the maximum principal strain. However, in the biaxial stretching range (both  $\varepsilon_1$  and  $\varepsilon_2$  are positive), necking occurs mainly in a direction perpendicular to the major

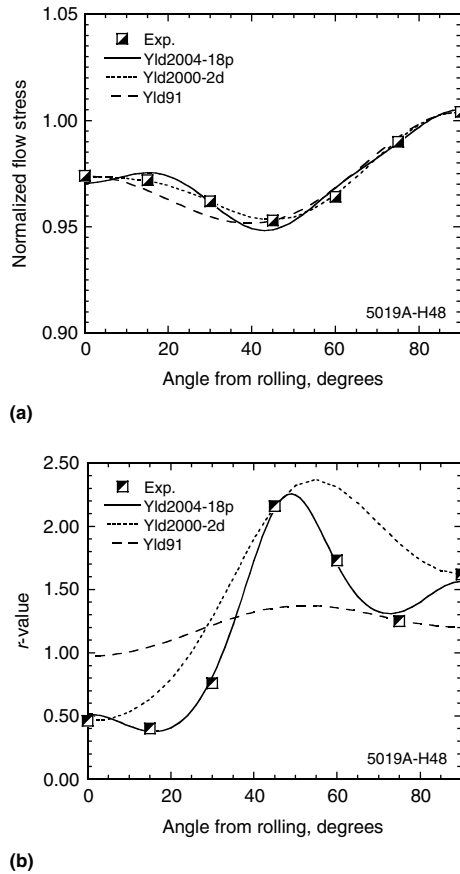

principal strain, which corresponds to the assumption of Eq 28. The product of the three quantities within the square brackets on the left side of Eq 28 must be constant. The first quantity ( $1 - D$ ) is related to the imperfection, and it decreases when D increases. However, the two other quantities tend to balance the equation. Because of the smaller thickness, there is more plastic deformation and consequently more plastic work in the necking band than in the homogeneous region. Therefore, the ratio  $h(\bar{\varepsilon}^l)/h(\bar{\varepsilon})$  becomes larger than 1. In addition, it has been shown (Ref 70) that the stress state in the imperfection moves toward a plane-strain state. Thus, the ratio  $\bar{\sigma}_1^l/\bar{\sigma}_1$  also increases, because the yield stress is at a maximum stationary value for plane strain. As a result, the increasing defect size is counterbalanced by two types of material hardening. The first one is strain hardening, whereas the second one, termed yield-surface shape hardening (Ref 71), is related to the yield surface shape. In particular, it has been shown that the ratio  $P = \sigma_p/\sigma_b$  of the plane-strain to balanced biaxial yield stresses is a good parameter to evaluate sheet stretchability (Ref 71). When this ratio is much larger than 1, as it is for an isotropic von Mises material ( $P \approx 1.15$ ), the predicted limit strain for balanced biaxial stretching is very large. However, the isotropic Tresca material, for which  $P = 1$ , exhibits a very low forming limit for the same strain path (Ref 72). For plane-strain tension, the ratio  $\bar{\sigma}_1^l/\bar{\sigma}_1$  is always equal to 1, regardless of the yield surface shape, and Eq 28 becomes:

$$(1 - D) \frac{h(\bar{\varepsilon}^l)}{h(\bar{\varepsilon})} = 1 \quad (\text{Eq 29})$$

This explains why the plane-strain deformation state always leads to the lowest forming limit. Materials cannot take advantage of the yield-surface shape-hardening effect in this deformation state, and only strain hardening is available to counterbalance the imperfection growth.

The previous analysis can also be used to explain qualitatively the effects of strain-rate sensitivity and kinematic hardening on formability. For strain-rate-sensitive materials, the left side of Eq 28 is multiplied by an additional (strain-rate) hardening term,  $(\dot{\varepsilon}^l/\dot{\varepsilon})^m$ , where  $m$  is the strain-rate sensitivity parameter. Because the strain rate is larger in the necking band than in the homogeneous region, this parameter is larger than 1, when  $m$  is positive, and therefore tends to stabilize plastic flow. If kinematic hardening applies, the yield surface moves toward the stress or strain-rate direction without changing its shape. This has the effect of decreasing the ratio P and consequently the forming limit, as predicted by Tvergaard (Ref 73).

Needleman and Triantafyllidis (Ref 74) showed that the imperfection can be attributed to material heterogeneities. In particular, it can be viewed as a difference in surface area transmitting the load. Hence, it can be assumed that internal damage mostly is responsible for the

**Fig. 7** Experimental results and predictions based on different yield functions of the (a) normalized tensile flow stress, and (b)  $r$ -value as a function of the angle between tensile and rolling directions for an aluminum alloy 5019A-H48 sheet sample

imperfection. In this context, damage is defined as the nucleation, growth, and coalescence of microvoids in a material due to plastic deformation. Studies of damage based on microscopic observations and probability calculations have shown that the order of magnitude of  $D$  in Eq 28 for typical commercial alloys is 0.4% (Ref 75–77). In the following discussion, the value of  $1-D = 0.996$  has been used to quantitatively characterize the imperfection.

Figure 8 shows an FLC computed for a 2008-T4 alloy sheet sample using two yield surfaces

**Fig. 8** Experimental forming-limit curve for an aluminum alloy 2008-T4 sheet sample (data points), and calculated curves based on the Yld89 (a special case of Yld2000-2d) yield function (solid line) and a crystal-plasticity model (dashed line).  $A = 447$  MPa (65 ksi);  $B = 248$  MPa (36 ksi);  $C = 4.3$  (Voce coefficients in Eq 8). Assumed initial imperfection size,  $t^0/t = 0.996$ . Source: Ref 78

(Ref 78). The first yield condition was described with the function Yld89 (Ref 36), a particular case of Yld2000-2d. The second yield condition was based on the Bishop and Hill (Ref 16) crystal-plasticity model. The same Voce-type work-hardening law, Eq 8, was used for both simulations. Both predictions are in good agreement with experimental data. In the stretching range, the imperfection orientation was assumed to be perpendicular to one of the orthotropic axes (rolling or transverse direction). The FLC was the lowest of the two curves calculated for the major strain either in the rolling or in the transverse direction. Experience in such computations shows that, for weakly textured materials, the forming limit is minimal for either case. However, for strongly textured aluminum alloy sheet, this is not necessarily the case. The influence of texture and microstructure on the FLC has been investigated by many authors (Ref 79–87).

**Stress-Based Forming-Limit Curves.** The previous discussion assumed that deformation occurs along linear strain paths, that is,  $\rho = d\epsilon_2/d\epsilon_1$  is constant. In practice, particularly for multistep forming, this is not the case. Moreover, it was shown by Kikuma et al. (Ref 88) that nonlinear strain paths have an influence on the FLC. Kobayashi et al. (Ref 89) and Graf and Hosford (Ref 90, 91) showed that the FLC strongly depends on the strain path for steel and aluminum alloy sheets, respectively. The characterization of forming limits in strain space is therefore a practical challenge for complex forming processes due to this sensitivity.

For computational purposes, one of the most promising solutions for dealing with strain path

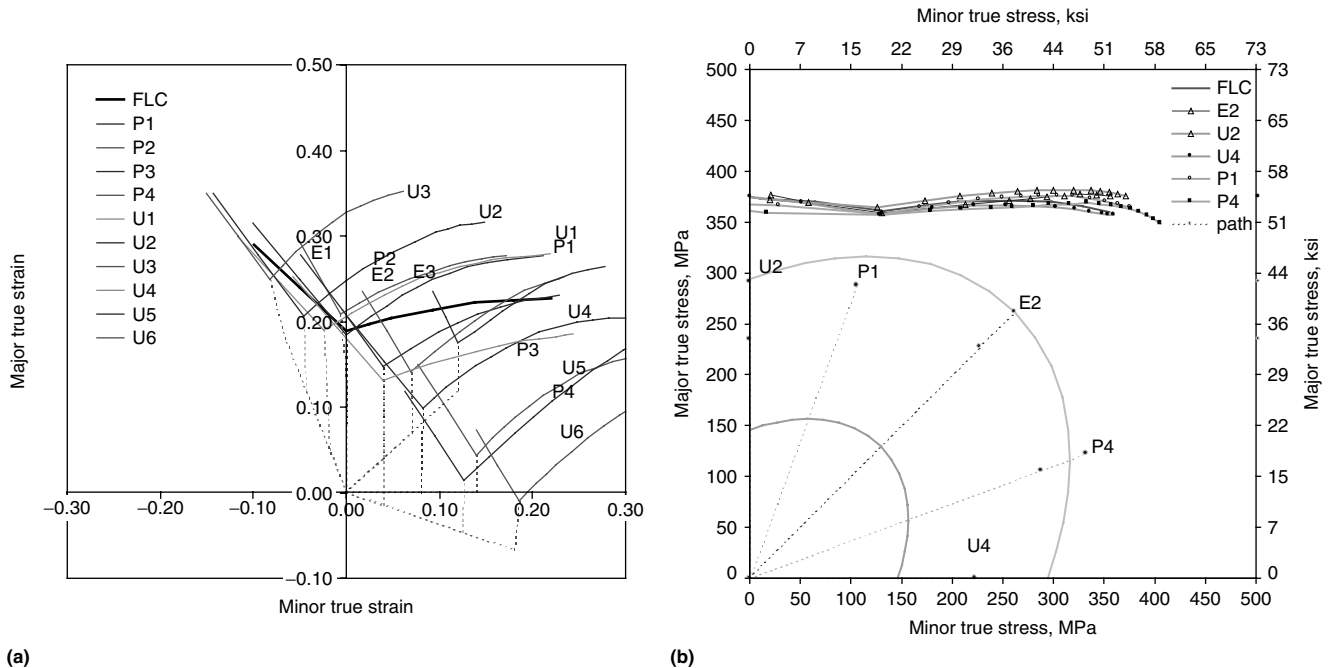

effects on the FLC is to use a stress-based approach, as proposed by Kleemola and Pelkkikangas (Ref 92), Arrieux et al. (Ref 93), Stoughton (Ref 94), and Stoughton and Yoon (Ref 95). These authors have shown that the FLC in stress space is path-independent and should be suitable to the analysis of any forming problem. As can be seen in Fig. 9, the FLCs described in strain space with different prestrains are mapped to a single curve in stress space. This verifies the path independence of the stress-based FLC. Recently, Kuwabara et al. (Ref 96) measured the stress state near the forming limit of tube deformed using internal pressure and end feed under proportional and nonproportional loading conditions. These authors confirmed that the forming limit as characterized by the state of stress is insensitive to the loading history.

Although not practical in a press shop, the stress-based FLC can be very effective when it is used to assess the safety margins in finite element simulations of forming processes. In order to compute the stress-based FLC, a representation of the forming-limit behavior for proportional loading in strain space, that is, the locus of principal strains, is specified as follows:

FLC (strain-based)

$$\equiv \begin{bmatrix} e_1^{\text{FLC}} \\ e_2^{\text{FLC}} \end{bmatrix} = e_1^{\text{FLC}}(\rho) \begin{bmatrix} 1 \\ \rho \end{bmatrix} \quad (\text{Eq 30})$$

where  $e_1^{\text{FLC}}$  and  $e_2^{\text{FLC}}$  are the coordinates of the FLC for linear strain paths, that is, major and minor principal strains. These points can be either measured or calculated, for instance, with the MK model. The strain path  $\rho = e_2^{\text{FLC}}/e_1^{\text{FLC}}$  is consistent with the definition in the previous

**Fig. 9** Effect of strain path on forming-limit curves (FLCs). (a) Strain-based FLC (exhibiting a path effect). (b) Stress-based FLC (limited path effect). Source: Ref 95

section and can vary in the range  $\rho = [-1, +1]$ . Because Eq 30 is assumed to accurately characterize the strain-based forming limit under proportional loading, it can be used with a plasticity model (yield function and strain hardening) to calculate the path-independent stress-based FLC, which can be similarly represented as:

$$\text{FLC (stress-based)} = \begin{bmatrix} \sigma_1^{\text{FLC}} \\ \sigma_2^{\text{FLC}} \end{bmatrix} = \sigma_1^{\text{FLC}}(\alpha) \begin{bmatrix} 1 \\ \alpha \end{bmatrix} \quad (\text{Eq 31})$$

In Eq 31,  $\alpha$  is the ratio of the minor to the major principal stresses ( $\sigma_2^{\text{FLC}}/\sigma_1^{\text{FLC}}$ ) of the stress-based FLC.

Although this FLC is assumed to be path-independent, the stresses calculated in the finite element (FE) analysis are path-dependent variables. Therefore, it is necessary to monitor the stress state at each step of the computation and determine if it is below or above the stress-based FLC. For this purpose, it is convenient to use a single parameter to monitor the formability margin, as follows (Ref 95):

$$\gamma_c = \frac{\bar{\sigma}(\sigma_{ij})}{h(\bar{\epsilon}^{\text{FLC}})} \quad (\text{Eq 32})$$

where:

$$\bar{\epsilon}^{\text{FLC}} = \frac{e_1^{\text{FLC}}(1 + \rho)}{\frac{\partial \bar{\sigma}}{\partial \sigma_{11}} + \frac{\partial \bar{\sigma}}{\partial \sigma_{22}}} \quad (\text{Eq 33})$$

In Eq 32,  $\gamma_c$  is a single stress-scaling factor representing the degree of formability according to the criteria:

$$\begin{aligned} \gamma_c < 1 & \quad \text{safe} \\ \gamma_c > 1 & \quad \text{necked (failure occurs)} \end{aligned} \quad (\text{Eq 34})$$

The formability margin as defined previously is based on the assumption that the forming limit is isotropic in the plane of the sheet. This assumption justifies the use of principal stresses and the representation of the forming limit as a curve in a two-dimensional diagram. In general, Graf and Hosford (Ref 90, 91) and others have shown that the forming limit is anisotropic. The method to deal with anisotropic data in stress-based FLC is explained in Ref 95.

### Compressive Instability

Wrinkling occurs when a blank is subjected to compressive stresses during the forming process, as, for instance, in the flange of a cup during drawing, triggered by the elastoplastic buckling of the thin structure. Although the failure limit due to plastic flow localization can be simply defined by the FLC at each point of a continuum, the wrinkling limit cannot be defined with simple variables such as strain, stress, and thickness. Buckling is also strongly affected by the mechanical properties of the sheet material, the geometry of the blank, and contact conditions. The analysis of wrinkling initiation and growth is

therefore difficult to perform due to the complex synergistic effects of the controlling parameters. Furthermore, commonly observed in instability phenomena, small variations of the parameters can result in widely different wrinkling behaviors. In the face of these difficulties, the study of wrinkling has generally been conducted case by case. A unique wrinkling criterion, which could be used effectively for various sheet-forming processes, has not been proposed yet.

Most of the studies related to wrinkling were carried out experimentally or analytically before the numerical simulation of stamping processes (Ref 97–99). An analytical bifurcation can give a useful estimate of the elastoplastic buckling of a plate with a basic geometrical shape and subjected to simple boundary conditions. This analysis, however, cannot be employed in general sheet metal forming processes. With the rapid development of computing power, wrinkling has also been studied using the FE method. Wrinkling can be analyzed in the same way as most buckling problems, that is, assuming a nonlinear elastic material behavior and ignoring complex contact conditions. Because wrinkling occurs in the plastic region, for a more realistic approach, the computations need to be based on an elastoplastic material model and take into account the complex contact conditions inherently present in sheet-forming processes.

Two types of buckling analyses are performed with the FE method: a bifurcation analysis of a structure without imperfection (Ref 100–103) and a nonbifurcation analysis, which assumes an initial imperfection or disturbing force due to load eccentricities (Ref 104–108). Because the FE analyses of sheet metal forming processes involve strong nonlinearities in geometry, material, and contact, convergence problems are frequently observed. Nonbifurcation analyses sometimes lead to reasonable results, because all real structures have inherent imperfections, such as material nonuniformity or geometric unevenness. Thus, most wrinkling analyses have been carried out using a nonbifurcation analysis. However, the results obtained from a nonbifurcation analysis are sensitive to the amplitude of the initial imperfection, which is chosen arbitrarily. As a result, bifurcation algorithms have been implemented into the FE method in order to analyze more rigorously the wrinkling behavior of sheet metal during forming (Ref 102, 103).

A number of studies have been devoted to the plastic buckling problem as a bifurcation phenomenon. The buckling of a column or a compressed circular plate and the wrinkling of a deep-drawn cup are typical examples of bifurcation problems. Shanley (Ref 109) first showed that the buckling load of a centrally compressed short column coincides theoretically with the tangent modulus. Hill (Ref 110) later generalized Shanley's concept and established a uniqueness criterion for the mathematical solution of elastic-plastic solids. This theory is now widely accepted in the analysis of bifurcation problems. Hutchinson (Ref 111)

specialized Hill's bifurcation criterion (Ref 110) to a class of loadings characterized by a single parameter and studied the postbifurcation behavior associated with the lowest possible bifurcation load. He showed that the initial slope of the load-deflection curve governs the material behavior in only a very small neighborhood of the bifurcation point, and that the rates of change of the instantaneous moduli at bifurcation have a major effect on the postbifurcation behavior. Prebuckling and postbuckling analyses were carried out with an FE method by incorporating the arc-length control scheme (Ref 100). In the bifurcation problem (Fig. 10), the stiffness matrix of the linearized FE equation becomes singular at a bifurcation point, and the Newton-Raphson solver cannot proceed further. Riks (Ref 100) proposed the continuation method by which the postbifurcation analysis can be carried out along the secondary solution branch (path) and implemented it for the buckling of elastic shell structures. In the work of Kim et al. (Ref 103), the continuation method was introduced in order to analyze the initiation and growth of wrinkles in deep drawing processes. A brief summary of the Riks method applied to sheet metal forming simulations is summarized as follows.

For a conservative system, the change of the total potential energy,  $\Delta\Pi$ , due to an admissible variation  $\delta\mathbf{u}$  of the displacement field  $\mathbf{u}$  can be written as:

$$\Delta\Pi(\mathbf{u}, \delta\mathbf{u}) = \frac{\partial\Pi}{\partial u_i} \delta u_i + \frac{1}{2} \frac{\partial^2\Pi}{\partial u_i \partial u_j} \delta u_i \delta u_j + \dots \quad (\text{Eq 35})$$

The second variation term must be positive definite for a stable system, a condition that can be written as:

$$\frac{\partial^2\Pi}{\partial u_i \partial u_j} \delta u_i \delta u_j = \mathbf{K}_{ij} \delta u_i \delta u_j > 0 \quad (\text{Eq 36})$$

where  $\mathbf{K}_{ij}$  represents the component of the tangent stiffness matrix  $\mathbf{K}$ . Therefore, the stability limit is reached when matrix  $\mathbf{K}$  ceases to be

**Fig. 10** Schematic illustration of solution paths in load-displacement ( $P$ - $u$ ) space for bifurcation-type problems

positive definite, that is, when:

$$\det[\mathbf{K}] = 0 \quad (\text{Eq 37})$$

In sheet metal forming process simulations, it is difficult to find the exact bifurcation point, because the control parameters in most of the problems are based on displacements. As a consequence, the determinant in Eq 37 changes sign abruptly within one incremental step in implicit analyses. The bifurcation point is, therefore, found by checking each value of the diagonal terms of a triangular form of the stiffness matrix.

The FE solution past the bifurcation point should not be the primary branch (path) but the secondary or bifurcated branch (path). In most of the bifurcation problems, the eigenvector is orthogonal to the primary branch. Thus, the increment of the nodal displacement field along the secondary branch  $\Delta \mathbf{u}^s$  can be simply taken as (Ref 100–103, 112, 113):

$$\Delta \mathbf{u}^s = \chi \mathbf{v} \quad (\text{Eq 38})$$

In Eq 38,  $\chi$  is a positive scalar, which should be determined, and  $\mathbf{v}$  is an eigenvector at a singular point, that is, calculated from the matrix identity:

$$\mathbf{K} \mathbf{v} = 0 \quad (\text{Eq 39})$$

In Eq 38, the trial increment  $\Delta \mathbf{u}^s = \mathbf{v}$  is used as an initial estimate for the Newton-type solution scheme, and it is updated during the iterations. The effect of magnitude of  $\chi$  on the wrinkling behavior is, therefore, eliminated. The details of this method are discussed in Ref 102 and 103.

### Springback

Springback refers to the undesirable shape change due to the release of the tools after a sheet-forming operation. Previous studies indicated that the final part shape after springback depends on the amount of elastic energy stored in the part during forming (Ref 114–119). Unfortunately, the elastic energy stored is a function of the process parameters, geometry of the tools and the blank, friction conditions, and material behavior. Moreover, the prediction of springback is very sensitive to the numerical parameters used in the simulations (Ref 120, 121). Therefore, predicting and compensating springback are very complicated tasks. The analytical and FE approaches for the prediction of springback were very well summarized in Ref 122 (see also the article “Springback” in this Volume).

The elastic modulus and yield strength are the first-order material parameters that influence springback. This can be perceived intuitively by considering a stress-strain curve. The amount of recoverable stored energy,  $\Delta E_r \cong \sigma \epsilon = \sigma^2 / E$ , decreases when the Young's modulus increases (0 for a rigid-plastic material) and the yield strengths decreases. Aluminum alloys have similar yield strengths but lower

elastic moduli than mild steels and consequently tend to generate more springback. However, other material parameters have an effect as well. Geng and Wagoner (Ref 123) discussed the importance of plastic anisotropy and the role of the yield surface. Time-dependent springback was investigated by Wagoner et al. (Ref 124) for a 6022-T4 aluminum alloy sheet sample. This effect was incorporated in finite element (FE) model using constitutive equations involving creep deformation (Ref 125).

During springback, when the tools are removed from a formed part, the material unloads elastically and, depending on the geometry, some elements can experience reloading in the reverse direction even beyond the yield limit. This plastic deformation can, in turn, influence the amount of springback. Due to the Bauschinger effect discussed previously, that is, the yield stress for reverse loading is lower than the flow stress just before unloading, the springback can be altered. Therefore, it is often necessary to account for the Bauschinger effect in springback simulations. The isotropic hardening is no longer valid, and an effective way to model this effect is to assume that the yield surface translates in stress space. This assumption, called kinematic hardening, was introduced by Prager (Ref 126), and some modifications were proposed by Ziegler (Ref 127). In order to describe the expansion and translation of the yield surface during plastic deformation, the combination of isotropic and kinematic hardening is also commonly used (Ref 128). Other approaches based on two or multiple embedded yield surfaces (Ref 129–131) account for the Bauschinger effect as well. Because the model proposed by Chaboche built on a single yield surface, its use in FE simulations is more cost-effective compared to the more sophisticated multisurface models. In addition to the Bauschinger effect, a transient hardening behavior is also observed during reverse loading, and some of the aforementioned models can account for this phenomenon. In particular, the Bauschinger effect as well as its associated transient behavior, which result from dislocation pattern reorganization, were effectively and elegantly modeled by Teodosiu and Hu (Ref 20).

A formulation for kinematic hardening that can accommodate any yield function is well summarized in Ref 132 to 134. Assuming a homogenous yield function  $\phi$  of degree  $a$ , translated in stress space by the backstress  $\boldsymbol{\alpha}$ , a tensorial state variable, the yield condition can be expressed as:

$$\phi(\sigma_{ij} - \alpha_{ij}) - \bar{\sigma}_{iso}^a = 0 \quad (\text{Eq 40})$$

where  $\sigma_{ij}$  are the components of the Cauchy stress tensor, and  $\bar{\sigma}_{iso}$  is the stress measuring the size of the yield surface. The rate of plastic work,  $\dot{w}$ , dissipated during deformation becomes:

$$\dot{w} = \sigma_{ij} \dot{\epsilon}_{ij} = (\sigma_{ij} - \alpha_{ij}) \dot{\epsilon}_{ij} + \alpha_{ij} \dot{\epsilon}_{ij} \quad (\text{Eq 41})$$

where  $\dot{\epsilon}_{ij}$  are the components of the strain rate (or rate of deformation) tensor. The effective quantities are now defined considering the following modified plastic work-equivalence relationship:

$$\dot{w}_{iso} = (\sigma_{ij} - \alpha_{ij}) \dot{\epsilon}_{ij} = \bar{\sigma}_{iso} \dot{\bar{\epsilon}} \quad (\text{Eq 42})$$

where  $\dot{\bar{\epsilon}}$  is the effective plastic strain rate. As for isotropic hardening, the normality rule is assumed to hold, and the model is complete with the definition of an evolution equation for the backstress.

### Finite Element Modeling

Nonlinear FE methods are becoming very popular in sheet metal forming process simulations. A problem is nonlinear if the force-displacement relationship depends on the current state, that is, on current displacement, force, and stress-strain relationship:

$$\mathbf{P} = \mathbf{K}(\mathbf{P}, \mathbf{u}) \mathbf{u} \quad (\text{Eq 43})$$

where  $\mathbf{u}$  is a displacement vector,  $\mathbf{P}$  a force vector, and  $\mathbf{K}$  the stiffness matrix. Linear problems form a subset of nonlinear problems. For example, in classical linear elastostatics, this relationship can be written in the form:

$$\mathbf{P} = \mathbf{K} \mathbf{u} \quad (\text{Eq 44})$$

where the stiffness matrix  $\mathbf{K}$  is independent of both  $\mathbf{u}$  and  $\mathbf{P}$ . If the matrix  $\mathbf{K}$  depends on other state variables, such as temperature, radiation, etc., but does not depend on displacement or loads, the problem is still linear. Similarly, if the mass matrix is constant, the following dynamic problem is also linear:

$$\mathbf{P} = \mathbf{M} \ddot{\mathbf{u}} + \mathbf{K} \mathbf{u} \quad (\text{Eq 45})$$

There are three sources of nonlinearities: material, geometry, and boundary condition. The material nonlinearity results from the nonlinear relationship between stresses and strains due to material plasticity. Geometric nonlinearity results from the nonlinear relationship between strains and displacements or the nonlinear relationship between stresses and forces. If the stress measure is energetically conjugate to the strain measure, both sources of nonlinearity have the same form. This type of nonlinearity is mathematically well defined but often difficult to treat numerically. Boundary conditions such as contact or friction are also sources of nonlinearities. This type of nonlinearity manifests itself in several real-life situations, for instance, in metal forming, gears, interfaces of mechanical components, pneumatic tire, and crash. A load on a structure causes nonlinearity if it changes with the displacement and deformation of the structure (such as pressure loading). Sheet metal forming processes include all of these three types of nonlinearities, in particular, elastoplastic material behavior,

large rotations, and contacts between the tools and the blank.

### General Kinematics

The kinematics of deformation can be described by Lagrangian, Eulerian, and Arbitrary Lagrangian-Eulerian (ALE) formulations. In the Lagrangian method, the FE mesh is attached to the material and moves through space along with the material. In the Eulerian formulation, the FE mesh is fixed in space, and the material flows through the mesh. In the ALE formulation, the grid moves independently from the material, yet in a way that spans the material at any time. The Lagrangian approach can be further classified in two categories: the total and the updated Lagrangian methods. In the total Lagrangian approach, equilibrium is expressed with the original undeformed reference frame, while, in the updated Lagrangian approach, the current configuration acts as the reference frame. In the latter, the true or Cauchy stresses and an energetically conjugate strain measure, namely, the true strain, are used in the constitutive relationships. The updated Lagrange approach is useful in:

- Analyses of shell and beam structure in which rotations are large so that the nonlinear terms in the curvature expressions may no longer be neglected
- Large strain-plasticity analyses in which the plastic deformations cannot be assumed to be infinitesimal

In general, this approach can be used to analyze structure where inelastic behavior causes large deformations. The (initial) Lagrangian coordinate frame has little physical significance in these analyses, because inelastic deformations are, by definition, permanent. Therefore, the updated Lagrangian formulation is appropriate for the simulations of sheet metal forming processes. For these analyses, the Lagrangian frame of reference is redefined at the last completed iteration of the current increment. The variational form of the equation for the static problem in the updated Lagrangian approach is given as:

$$\int_V \frac{\partial \delta u_i}{\partial x_j} \sigma_{ij} dV - \int_\Gamma \delta u_i f_i d\Gamma = 0 \quad (\text{Eq 46})$$

where  $V$  is the volume considered,  $\Gamma$  is the surface on which the traction components  $f_i$  are imposed, and  $\sigma_{ij}$  is the Cauchy stress. The linearized variational form of Eq 46 needed for the Newton-Raphson numerical solver can be written as:

$$\begin{aligned} & \int_V \frac{\partial \delta u_i}{\partial x_j} C_{ijkl} \frac{\partial \Delta u_k}{\partial x_l} dV + \int_V \frac{\partial \delta u_i}{\partial x_j} \sigma_{jl} \frac{\partial \Delta u_i}{\partial x_l} dV \\ & = - \int_V \frac{\partial \delta u_i}{\partial x_j} \sigma_{ij} dV + \int_\Gamma \delta u_i f_i d\Gamma \end{aligned} \quad (\text{Eq 47})$$

The left side of Eq 47 corresponds to the material and geometric stiffness, while its right side is associated with the internal and external force vectors, respectively. In the FE method, the left side dominates the convergence rate, and the right side directly controls the accuracy of the solution.

### Element Formulation

Finite element analyses of sheet metal forming processes can be broadly classified into three categories according to the element types used: membrane analysis (plane stress without bending stiffness), shell analysis (plane stress with bending stiffness), and continuum analysis (general stress state). For sheet metal forming simulations, the shell analysis is the most popular.

Wang and Budiansky (Ref 135) suggested an elastic-plastic membrane formulation based on the plane-stress assumption for forming sheet metal exhibiting normal anisotropy (also called planar isotropy). This type of anisotropy characterizes a sheet with identical properties in any direction in its plane but different properties in its normal direction. These authors provided an example on the axisymmetric stretching of a sheet with a hemispherical punch. Yang and Kim (Ref 136) derived a membrane-based rigid plastic FE method incorporating material and geometric nonlinearities for materials exhibiting planar anisotropy, which was described by Hill's 1948 yield criterion. Hora et al. (Ref 137) analyzed the forming of an arbitrary-shaped auto-body panel, which is a drawing-dominant process, based on membrane elements. Yoo et al. (Ref 138) suggested the bending energy augmented membrane approach in order to overcome the inherent numerical buckling occurring due to the lack of rotational stiffness in the membrane analysis. Kubli and Reissner (Ref 139) analyzed complicated panels, considering bending effects using the uncoupled solutions of membrane and bending analyses. However, the membrane analysis provides insufficient information for the treatment of bending-dominant forming processes.

Two basic approaches concerning the development of nonlinear shell FEs can be identified: classical shell elements and degenerated solid elements. The classical shell elements are directly based on the governing differential equations of an appropriate shell theory. Despite the potential economy of such elements, the development of nonlinear shell elements involves mathematical complexities. The degenerated solid element, which was initiated by Ahmad et al. (Ref 140) for the linear analysis of continuum formulation, is reduced in dimensionality by direct imposition of kinematics and constitutive constraints. The works of Ramm (Ref 141), Parish (Ref 142), Hughes and Liu (Ref 143, 144), Dvorkin and Bathe (Ref 145), and Liu et al. (Ref 146), among many others, constitute representative examples of this methodology carried out in the most general way for the nonlinear regime. The books of Bathe

(Ref 147), Hughes (Ref 148), and the thesis of Stanley (Ref 149) offer a comprehensive overview of the degenerated solid approach and related methodologies. A point frequently made for the degenerated approach is that it avoids the mathematical complexities associated with the classical shell theory and hence is much easier for numerical implementation. Similarly, Belytschko et al. (Ref 150), Hallquist et al. (Ref 151), and Belytschko and Leviathan (Ref 152) developed one-point quadrature shell elements for the explicit FE methods applicable to both linear and nonlinear plate and shell analyses.

Finite element analyses using shell elements have shown a remarkable progress in the last few years with respect to both accuracy and efficiency. Recently, Cardoso and Yoon (Ref 153, 154) suggested new one-point quadrature elements considering element warping and thickness strain. In addition, Batoz et al. (Ref 155) suggested a membrane-bending FE model with membrane effects represented by constant-strain triangular elements and the bending effect represented by discrete Kirchhoff triangular elements. Alves de Sousa et al. (Ref 156) recently proposed one-point quadrature solid-shell elements that have eight nodes and consider multiple integration points through the thickness within one element layer, which can be applied for springback analysis. The application of shell elements to sheet-forming simulations can be found in Ref 154 and 157 to 161. The kinematics for a continuum-based shell is summarized as follows.

**Kinematic Hypotheses.** The physical spatial region of the shell element is described with coordinates  $(\xi, \eta, \zeta)$ , as shown in Fig. 11. The current position vector  $\mathbf{x}$  of a generic point of the shell is defined by:

$$\mathbf{x}(\xi, \eta, \zeta) = \bar{\mathbf{x}}(\xi, \eta) + \bar{\zeta} \bar{\mathbf{x}}(\xi, \eta) \quad (\text{Eq 48})$$

where  $\bar{\zeta}(\xi, \eta, \zeta) = \zeta / t(\xi, \eta) / 2$ .

In Eq 48, the reference surface  $\bar{\mathbf{x}}(\xi, \eta)$  is chosen to be the midsurface, that is  $\bar{\mathbf{x}}(\xi, \eta) = \mathbf{x}(\xi, \eta, \zeta = 0)$ . The symbol  $\bar{\mathbf{x}}$  is the unit fiber vector emanating from the midsurface, and  $t$  is the shell thickness. Equation 48 is often referred to as straight normal assumption. Equation 48 prescribes a linear  $\bar{\zeta}$ -dependence, which constrains the unit fiber vector to remain straight but not necessarily normal to the reference surface. Equation 48 can be interpolated from the node positions to any point of a shell element through the shape functions:

$$\mathbf{x}(\xi, \eta, \zeta) = \sum_{p=1}^{N_{en}} N_p(\xi, \eta) \{ \bar{\mathbf{x}}_p + \bar{\zeta} \bar{\mathbf{x}}_p \} \quad (\text{Eq 49})$$

where:

$$\bar{\zeta}(\xi, \eta, \zeta) = \zeta \sum_{p=1}^{N_{en}} N_p(\xi, \eta) t_p$$

In the previous equation, the subscript "p" ranges over the number of nodes per element  $N_{en}$ . The shape functions,  $N_p$ , are typically selected

from the Lagrange interpolation family. The displacement,  $\mathbf{u}$ , of a generic point is the difference between its current position,  $\mathbf{x}$ , and its reference position,  $\mathbf{X}$ :

$$\mathbf{u}(\xi, \eta, \tilde{z}) = \mathbf{x}(\xi, \eta, \tilde{z}) - \mathbf{X}(\xi, \eta, \tilde{Z}) \quad (\text{Eq 50})$$

or

$$\mathbf{u}(\xi, \eta, \tilde{z}) = \bar{\mathbf{u}}(\xi, \eta) + \tilde{z}\bar{\mathbf{u}}(\xi, \eta) + (\tilde{z} - \tilde{Z})\bar{\mathbf{X}} \quad (\text{Eq 51})$$

where  $\mathbf{X}(\xi, \eta, \tilde{Z}) = \bar{\mathbf{X}}(\xi, \eta) + \tilde{Z}\bar{\mathbf{X}}(\xi, \eta)$ .

The displacement vector,  $\mathbf{u}$ , can be obtained by assuming that the fiber vector is inextensible. This assumption allows fiber vectors to rotate, but they cannot be stretched or contracted. Therefore,  $\bar{\mathbf{x}}$  remains a unit vector and the quantity  $\tilde{z} - \tilde{Z}$  in Eq 51 vanishes. By applying the straight normal kinematics  $\tilde{z} - \tilde{Z} = 0$  in Eq 51, the position of a continuum point is defined as:

$$\mathbf{u}(\xi, \eta, \tilde{z}) = \bar{\mathbf{u}}(\xi, \eta) + \tilde{z}\bar{\mathbf{u}}(\xi, \eta) \quad (\text{Eq 52})$$

or

$$\Delta\mathbf{u}(\xi, \eta, \tilde{z}) = \Delta\bar{\mathbf{u}}(\xi, \eta) + \tilde{z}\Delta\bar{\mathbf{u}}(\xi, \eta) \quad (\text{Eq 53})$$

with  $\Delta\mathbf{u} \cdot \bar{\mathbf{x}} = 0$ .

Equation 52 is referred to as the incremental rigid normal assumption. In addition, the kinematics of the shell element is defined in terms of the same shape functions introduced previously in Eq 49:

$$\mathbf{u}(\xi, \eta, \tilde{z}) = \sum_{p=1}^{N_{en}} N_p(\xi, \eta) \{\bar{\mathbf{u}}_p + \tilde{z}\bar{\mathbf{u}}_p\} \quad (\text{Eq 54})$$

where the six global incremental nodal variables at the  $p^{\text{th}}$  node are:

$$\Delta\mathbf{a}_p = [\Delta\bar{\mathbf{u}}_{1p} \ \Delta\bar{\mathbf{u}}_{2p} \ \Delta\bar{\mathbf{u}}_{3p} \ \Delta\bar{\mathbf{u}}_{1p} \ \Delta\bar{\mathbf{u}}_{2p} \ \Delta\bar{\mathbf{u}}_{3p}]^T \quad (\text{Eq 55})$$

**Static Hypotheses.** In addition to the kinematics, the static hypotheses are used to exploit the relative insignificance of the stress component acting directly on the reference surface. The first static hypothesis, zero normal stress, simply consists of eliminating this component whenever it explicitly appears in the governing equations:

$$\sigma_{33} = 0 \quad (\text{zero normal stress}) \quad (\text{Eq 56})$$

The second hypothesis is, in some sense, the time derivative of the zero normal stress because, if a quantity is identically zero, its derivative expressed in an appropriate frame should vanish as well:

$$\dot{\sigma}_{33} = 0 \quad (\text{zero normal stress rate}) \quad (\text{Eq 57})$$

For details, the reader is referred to Ref 161.

### Matrix Formulation

The assembled FE matrix of the linearized variational form in Eq 47 is obtained by replacing the incremental and variational displacements ( $\Delta\mathbf{u}$  and  $\delta\mathbf{u}$ ) by their discrete element approximation and by incorporating the kinematic and static hypotheses, Eq 53 and 57. Then, the resulting equation is integrated element-wise over the entire problem domain. Using the arbitrariness of the weighting coefficients, the system of equations for the nodal displacement increments are:

$$(\mathbf{K}^{\text{matl}} + \mathbf{K}^{\text{geom}})\Delta\mathbf{a} = \mathbf{F}^{\text{ext}} - \mathbf{F}^{\text{int}} \quad (\text{Eq 58})$$

In Eq 58,  $\mathbf{F}^{\text{ext}}$  is the assembled external force vector,  $\mathbf{F}^{\text{int}}$  is the assembled internal force vector, and  $\mathbf{K}^{\text{matl}}$  and  $\mathbf{K}^{\text{geom}}$  are the assembled material and geometric stiffness matrices, respectively. Detailed information about Eq 58 is given in Ref 147 and 148.

Equation 58 forms a system of equations for the so-called implicit method. By ignoring the left side, that is,  $\mathbf{F}^{\text{ext}} - \mathbf{F}^{\text{int}} = 0$ , Eq 58 becomes an equation for the so-called explicit method. Numerical solution schemes are often referred to as being explicit or implicit. When a direct computation of the dependent variables can be made in terms of known quantities, the computation is said to be explicit. In contrast, when the dependent variables are defined by a coupled set of equations, an iterative technique is needed to obtain the solution, such as for Eq 58, and the numerical method is said to be implicit. As mentioned in the section "General Kinematics" in this article, the right side of Eq 58 controls the solution accuracy, and the left side dominates the convergence rate. Because the explicit method does not involve the left side, stiffness matrix assembling and convergence checking are not required. Therefore, it is very attractive when

convergence is a big hurdle, as it may be for complicated sheet metal stamping problems. However, the explicit solution is only stable if the time step size is smaller than a critical value:

$$\Delta t \leq \Delta t^{\text{crit}} = \frac{2}{\omega_{\text{max}}} \quad (\text{Eq 59})$$

which guarantees the accuracy of the solution. Here,  $\omega_{\text{max}}$  is the largest natural frequency of the system (characteristics of the mesh size and material density). Usually, the explicit stable time step size is extremely small compared to the implicit solution (approximately 1000 smaller). Furthermore, the mesh size is proportional to  $1/\omega_{\text{max}}$ . Therefore, the stable time step size becomes smaller when the mesh size decreases. In particular, when mesh refinement is conducted during the analysis, mesh sizes become approximately one quarter smaller per one time of mesh refinement. Because the stable time step size in an explicit code is determined by the minimum element length, it causes the analysis time to be much longer. In contrast, the implicit solution is always stable; that is, the time step can be arbitrarily large for a linear problem. For nonlinear problems, the implicit time step size may need to become smaller according to convergence difficulties.

### Elastic-Plastic Stress Integration

Most rate-independent plastic models are formulated in terms of rate-type constitutive equations, for which the integration method has a considerable influence on the efficiency, accuracy, and convergence of the solution. In the simulation of sheet forming processes, the constitutive equation is integrated along an assumed deformation path. Among the infinite ways to assume the deformation path, the minimum plastic work path in homogeneous deformation has been found to have several advantages. Requirements for achieving minimum plastic work paths in homogeneous deformation are well documented in Ref 162 to 165. The minimum work path, which is also the proportional logarithmic (true) strain paths, is achieved under two conditions. First, the set of three principal axes of stretching is fixed with respect to the material; second, the logarithms of the principal stretches remain in a fixed ratio. The incremental deformation theory based on the minimum plastic work path enables convenient decoupling of deformation and rotation by the polar decomposition at each process increment. The resulting incremental constitutive law is frame-indifferent (objective), because the theory uses a materially embedded coordinate system. The incremental deformation theory is useful for the FE modeling of rigid-plastic and elastoplastic constitutive formulations. In rigid plasticity, the theory was introduced for process analyses by Yang and Kim (Ref 136), Germain et al. (Ref 166), Chung and Richmond (Ref 167, 168), and Yoon et al.

**Fig. 11** Continuum-based shell elements. (a) Construction of a typical shell element. (b) Shell geometry

(Ref 169). For elastoplastic materials, the incremental deformation theory has been successfully applied for materials exhibiting isotropy (Ref 170) and planar anisotropy (Ref 161, 171).

**Continuum Models.** The most popular scheme for stress integration is the predictor-corrector method (often called return mapping). This method is applied in two successive steps: the prediction step, during which a trial stress state is estimated, and the corrector step, during which a flow rule is applied by return mapping procedures in order to bring (project) the stress onto the yield surface or, in other words, to ensure the consistency condition (i.e., the stress state must be on the yield surface). During the return mapping procedure, a reasonable assumption for the deformation path must be imposed. A return mapping procedure was first introduced in the paper of Wilkins (Ref 172). The works of Ortiz and Pinsky (Ref 173) and Ortiz et al. (Ref 174) apply the closet point-projection method to perform the procedure in plane-stress conditions. Later, Ortiz and Simo (Ref 175) developed a new class of integration algorithms based on the cutting-plane approach. However, this approach has no clear physical meaning in the deformation path viewpoint. Recently, Yoon et al. (Ref 161) proposed the multistage return mapping method based on incremental deformation theory, which follows the minimum plastic work path. In this work, it was proven that, when the consistency condition and normality rule (strain increment normal to yield surface) are imposed, this new projection during the current unknown step becomes the closet point projection. The stress integration procedure is briefly summarized as follows.

The increment of the Cauchy stresses is given by applying the fourth-order elastic modulus tensor  $\mathbf{C}^e$  to the incremental second-order elastic strain tensor  $\Delta\boldsymbol{\varepsilon} - \Delta\boldsymbol{\varepsilon}^p$ :

$$\Delta\boldsymbol{\sigma} = \mathbf{C}^e(\Delta\boldsymbol{\varepsilon} - \Delta\boldsymbol{\varepsilon}^p) \quad (\text{Eq 60})$$

in which  $\Delta\boldsymbol{\varepsilon}$  and  $\Delta\boldsymbol{\varepsilon}^p$  are the total and plastic strain increments, respectively. The relationship in Eq 60 is assumed to be expressed in a material-embedded coordinate system. Therefore, it is objective with respect to (independent of) the material rotation. In order to follow the minimum plastic work path in the incremental deformation theory, the logarithmic plastic strain needs to remain normal to the yield surface at the representative stress state, that is:

$$\Delta\boldsymbol{\varepsilon}^p = \Delta\bar{\boldsymbol{\varepsilon}}^p \frac{\partial \bar{\boldsymbol{\sigma}}}{\partial \boldsymbol{\sigma}} = \gamma \mathbf{m} \quad (\text{Eq 61})$$

where  $\mathbf{m} = \partial \bar{\boldsymbol{\sigma}} / \partial \boldsymbol{\sigma}$  is a symbolic notation that represents the tensor of component  $m_{ij} = \partial \bar{\boldsymbol{\sigma}} / \partial \sigma_{ij}$ . The condition stipulating that the updated stress stays on the strain-hardening curve provides the following equation:

$$\begin{aligned} F(\lambda) &= \bar{\boldsymbol{\sigma}}(\boldsymbol{\sigma}_n + \Delta\boldsymbol{\sigma}) - h(\bar{\boldsymbol{\varepsilon}}_n^p + \lambda) \\ &= \bar{\boldsymbol{\sigma}}[\boldsymbol{\sigma}_n + \mathbf{C}^e(\Delta\boldsymbol{\varepsilon} - \lambda \mathbf{m})] - h(\bar{\boldsymbol{\varepsilon}}_n^p + \lambda) = 0 \end{aligned} \quad (\text{Eq 62})$$

where the subscript “n” denote quantities at step “n” in the simulation.

The predictor-corrector scheme based on the Newton-Raphson method is generally used to solve the nonlinear system in Eq 62 for  $\lambda = \Delta\bar{\boldsymbol{\varepsilon}}^p$ . However, while a mathematical solution to this equation does exist, it can be difficult to obtain numerically if the strain increment is not small enough. In the examples in the next section, a multistage return mapping procedure based on the control of the residual suggested by Yoon et al. (Ref 161) was employed. The proposed method is applicable to nonquadratic yield functions and general strain-hardening laws without a line search algorithm, even for a relatively large strain increment (10%). At the end of the step, when Eq 62 is solved, all kinematic variables and stresses are updated.

In order to consider the rotation of the anisotropic axes, a co-rotational coordinate system (constructed at each integration point), is

defined and initially coincides with the material symmetry axes. For the examples discussed in the section “Application Examples” in this article, it is assumed that the orthogonality of the anisotropy axes is preserved during sheet forming under the isotropic hardening assumption. This assumption is generally considered as appropriate in sheet-forming process simulations. From the polar decomposition theorem, the deformation of a material element represented by the deformation gradient tensor,  $\mathbf{F}$ , is the combination of a pure rotation,  $\mathbf{R}$ , and a pure stretch,  $\mathbf{U}$  ( $\mathbf{F} = \mathbf{R}\mathbf{U}$ ). The rotation of the anisotropy axes is updated incrementally at every step by the rotation amount ( $\mathbf{R}$ ) obtained from the polar decomposition (Fig. 12). For instance, if at the first step  ${}^0\boldsymbol{\lambda}$  and  ${}^0\boldsymbol{\mu}$  are the unit vectors coinciding with the rolling and transverse directions, respectively, the updated axes are given by:

$$\begin{aligned} \boldsymbol{\lambda} &= \mathbf{R} {}^0\boldsymbol{\lambda} \\ \boldsymbol{\mu} &= \mathbf{R} {}^0\boldsymbol{\mu} \end{aligned} \quad (\text{Eq 63})$$

**Crystal-Plasticity Models.** These models account for the deformation of a material by crystallographic slip and for the reorientation of the crystal lattice. The influence of crystal symmetry on elastic constants can be included, and the strain-hardening and cross-hardening effects between the slip systems can be incorporated through the use of state variables. Furthermore, a rate-dependent approach is also typically employed to relate the shear stresses and shear strains on the different slip systems. The kinematics of the model was summarized by Dao and Asaro (Ref 176). The deformation gradient,  $\mathbf{F}$ , is decomposed into a plastic deformation,  $\mathbf{F}^p$ , which is the summation of the shear strain for each slip system, and a combination of elastic deformation and rigid body motion of the crystal lattice,  $\mathbf{F}^e$ , as shown in Fig. 13, that is:

$$\mathbf{F} = \mathbf{F}^e \mathbf{F}^p \quad (\text{Eq 64})$$

**Fig. 12** Rotation of anisotropic axes during deformation.  $\mathbf{F}$ , deformation gradient tensor;  $\mathbf{R}$ , pure rotation;  $\mathbf{U}$ , pure stretch;  ${}^0\boldsymbol{\mu}$ , unit vector for transverse direction;  ${}^0\boldsymbol{\lambda}$ , unit vector for rolling direction

**Fig. 13** Multiplicative decomposition of deformation gradient. See text for description.

Because plasticity occurs by dislocation slip, the plastic deformation rate,  $\mathbf{L}^p$ , is determined by the summation of the shear strain contribution over all of the slip system (Ref 176):

$$\mathbf{L}^p = \sum_{(s)} \dot{\gamma}^{(s)} \mathbf{b}^{(s)} \mathbf{n}^{(s)} \quad (\text{Eq 65})$$

Here, (s) denotes a slip system,  $\mathbf{n}^{(s)}$  is the normal of the slip plane, and  $\mathbf{b}^{(s)}$  is the vector in the slip direction. Both vectors are orthogonal, that is,  $\mathbf{n}^{(s)} \times \mathbf{b}^{(s)} = \mathbf{0}$ , and are assumed to rotate with the elastic spin of the lattice. In general, these vectors are not unit vectors like in a phenomenological model because they are allowed to stretch. Using Eq 65, the symmetric and skew symmetric parts of  $\mathbf{L}^p$  the rate of deformation tensor  $\mathbf{D}^p$  and plastic spin  $\mathbf{W}^p$ , respectively, can be written as:

$$\mathbf{D}^p = 1/2(\mathbf{L}^p + \mathbf{L}^{pT}) = \sum_{(s)} \dot{\gamma}^{(s)} 1/2(\mathbf{b}^{(s)} \mathbf{n}^{(s)} + \mathbf{n}^{(s)} \mathbf{b}^{(s)})$$

$$\text{or } \mathbf{D}^p = \sum_{(s)} \dot{\gamma}^{(s)} \mathbf{P}_{(s)} \quad (\text{Eq 66})$$

$$\mathbf{W}^p = 1/2(\mathbf{L}^p - \mathbf{L}^{pT}) = \sum_{(s)} \dot{\gamma}^{(s)} 1/2(\mathbf{b}^{(s)} \mathbf{n}^{(s)} - \mathbf{n}^{(s)} \mathbf{b}^{(s)})$$

$$\text{or } \mathbf{W}^p = \sum_{(s)} \dot{\gamma}^{(s)} \mathbf{W}_{(s)} \quad (\text{Eq 67})$$

where the tensors  $\mathbf{P}_{(s)}$  and  $\mathbf{W}_{(s)}$  have been introduced for notational convenience.

Usually, the Cauchy or true stress,  $\boldsymbol{\sigma}$ , is employed for the stress integration. However, in this section, the Kirchhoff stress,  $\boldsymbol{\tau}$ , is considered. By ignoring the elastic volume change, the Cauchy stress is related to the Kirchhoff stress,  $\boldsymbol{\tau}$ , through the relationship  $\boldsymbol{\tau} = J\boldsymbol{\sigma}$ , where  $J$  is the determinant of  $\mathbf{F}^e$ . Writing the rate of deformation tensor as the sum of elastic and plastic parts, an objective stress rate,  $\dot{\boldsymbol{\tau}}$ , can be expressed as:

$$\dot{\boldsymbol{\tau}} = \mathbf{K} : \mathbf{D} - \sum_{(s)} \dot{\gamma}^{(s)} (\mathbf{K} : \mathbf{P}_{(s)} + \mathbf{W}_{(s)} \cdot \boldsymbol{\tau} - \boldsymbol{\tau} \cdot \mathbf{W}_{(s)})$$

$$= \mathbf{K} : \mathbf{D} - \sum_{(s)} \dot{\gamma}^{(s)} \mathbf{R}_{(s)} \quad (\text{Eq 68})$$

where  $\mathbf{K}$  is the fourth-order elastic modulus tensor, and  $\mathbf{D}$  is the rate of deformation tensor. Then, the resolved shear stress at the end of the time step becomes:

$$\tau_{t+\Delta t}^{(s)} = \tau_t^{(s)} + \Delta t \dot{\tau}^{(s)} = \tau_t^{(s)} + \Delta t \mathbf{R}_{(s)} : \mathbf{D} - \Delta t \sum_{(a)} \dot{\gamma}^{(a)} \mathbf{R}_{(s)} : \mathbf{P}_{(a)} \quad (\text{Eq 69})$$

where  $\mathbf{R}_{(s)} = \mathbf{K} : \mathbf{R}_{(s)} + \mathbf{W}_{(s)} \times \boldsymbol{\tau} - \boldsymbol{\tau} \times \mathbf{W}_{(s)}$ .

The resolved shear stress,  $\tau^{(s)}$ , also follows the rate-dependent hardening rule:

$$\tau^{(s)} = g^o \left( \frac{|\dot{\gamma}^{(s)}|}{\dot{\gamma}_o} \right)^m \text{sign}(\dot{\gamma}^{(s)}) \quad (\text{Eq 70})$$

where  $g^o$  is the shear yield stress on a slip system.

Finally, the resolved shear stress defined by Eq 69 and 70 must have the same value at  $t + \Delta t$ :

$$E^s(\dot{\gamma}^{(s)}) = \tau_t^{(s)} + \Delta t \mathbf{R}_{(s)} : \mathbf{D} - \Delta t \sum_{(a)} \dot{\gamma}^{(a)} \mathbf{R}_{(s)} : \mathbf{P}_{(a)} - g^o \left( \frac{|\dot{\gamma}^{(s)}|}{\dot{\gamma}_o} \right)^m \text{sign}(\dot{\gamma}^{(s)}) = 0 \quad (\text{Eq 71})$$

Equation 71 is a nonlinear equation. It is solved with the Newton-Raphson method after linearization (Ref 177), that is:

$$E^s(\dot{\gamma}^{(s)}) + \sum_{(a)} \frac{dE^s}{d\dot{\gamma}^{(a)}} d\dot{\gamma}^{(a)} = 0 \quad (\text{Eq 72})$$

### Ideal Forming Design Theory

Finite element (FE) methods are used mostly for analysis of boundary-value problems. This means that the problem is well set, with known tool and blank geometries, material and interface properties, and realistic stress- and displacement-imposed boundary conditions. This type of application of the method is referred to as FE analysis. However, in practice, the final shape of the product is imposed, and the manufacturing process needs to be designed around it. Therefore, in order to improve the conventional trial-and-error-based practices for optimizing forming processes, either by experiments or FE analysis, an FE design theory, called ideal forming theory, was proposed (Ref 167, 168, 178). The FE implementation is a time-efficient one-step code, providing not only the initial blank geometry but all the intermediate shapes and the entire load history necessary to achieve it, thus providing invaluable information about the ideal process parameters. This application is referred to as FE design.

In this theory, materials are prescribed to deform following the minimum plastic work path. The final product shape is specified, and the initial blank shape is obtained from the global extremum plastic work criterion as a one-step backward solution. Although the theory is general enough to accommodate any other form of constraints, the underlying physical assumption of this extremum work condition is that the strain gradients are minimized on the overall part, thus departing as much as possible from plastic flow localization modes. In order to consider local thinning effects due to friction, a method based on a modified extremum work criterion has also been developed (Ref 178). The ideal forming theory has been successfully applied for sheet-forming processes to optimize flat blanks (Ref 179–181) and also for bulk forming in steady (Ref 182–185) and nonsteady flows (Ref 186, 187).

When a sheet (or tube) is discretized with meshes and the surface tractions are approximated by point forces, the total plastic work,  $W$ ,

becomes a function of the initial and final configurations, assuming that the minimum plastic work path is imposed on each material element, that is:

$$W = W[\bar{\epsilon}(\mathbf{x}^i, \mathbf{X}^i)] = \iiint \bar{\sigma}(\bar{\epsilon}) \bar{\epsilon} dV_0 \quad (\text{Eq 73})$$

where  $\bar{\sigma}(\bar{\epsilon})$ ,  $\bar{\epsilon} = \int d\bar{\epsilon}$ , and  $V_0$  are the effective stress, the effective strain, and the initial volume of the part, respectively. The parameters  $\mathbf{x}^i$  and  $\mathbf{X}^i$  are the final and initial positions of the  $i$ th node in the global Cartesian coordinate system. As mentioned previously, in this method, the part shape ( $\mathbf{x}^i$ ) is prescribed, and the initial blank shape ( $\mathbf{X}^i$ ) is the output of the numerical simulation. Therefore, the optimization is performed with respect to the initial configuration. In the ideal forming theory, when the minimum plastic work path is imposed for each material element, the initial blank shape is obtained by optimizing the plastic work or, more specifically, by imposing  $dW/d\mathbf{X}^i = 0$ . Another term is added to this equation when friction is taken into account. In this optimization, constraints pertaining to the initial shape are also imposed. For instance, the initial blank must be on a given surface, for instance, a flat sheet, a cylindrical tube, and so on. In tube hydroforming, the preform shape must be straight with a uniform cross section if the tube is extruded. Therefore, the additional constraint is that each node-set in Fig. 14 must move the same amount in the  $\bar{X}_3$  direction. Because of the mathematical form of Eq 73, it is much more convenient to describe the material with a strain-rate potential (see the section “Strain-Rate Potentials” in this article), which emphasizes the importance of this type of material description, particularly applied to aluminum alloy products. The combination of plastic work optimization, material behavior, friction conditions, and initial shape constraints reduces to a system of nonlinear equations that can be solved for  $\mathbf{X}^i$  (corresponding to the initial blank shape), using a Newton-Raphson solver.

Of course, this theory is based on ideal deformation conditions. More realistic simulations can be achieved with FE analysis codes, but the ideal forming theory provides a quick and excellent initial mapping of the forming process needed to manufacture a product, thus limiting the number of costly experimental and FE analysis trials.

Fig. 14 Local Cartesian coordinate systems defined on an assumed cross section of the initial tube

## Application Examples

**Example 1: Shear Testing Simulation.** This first example pertains to the simulation of the simple shear test. This example illustrates the numerical testing and possible issues, such as implementation, input data, and so on, that should be addressed before performing the simulation of a complex forming operation. Simple examples also validate the choice of the constitutive models used in the simulations. In this particular example, the simple shear test shows that the constitutive response of material subjected to a given deformation mode (e.g., shear) can be well approximated using constitutive equations identified using information measured on different stress states (e.g., uniaxial tension or balanced biaxial tension).

Simple shear tests were conducted on a commercial-purity 1050-O and automotive 6022-T4 aluminum alloy sheet samples on a device similar to that shown in Fig. 4. The testing was performed in two specimen orientations, that is, with shear in the transverse direction (TD) or at 45° from the rolling direction (RD). The

1050-O sheet sample was 3 mm (0.12 in.) thick, and the shear specimen was 40 by 40 mm (1.6 by 1.6 in.), with a shear zone width of 8 mm (0.3 in.) (Fig. 15). The 6022-T4 sheet sample was 1 mm (0.04 in.) thick, and the shear specimen was 60 by 15 mm (2.4 by 0.6 in.), with a shear zone width of 3 mm (0.12 in.) (Fig. 15). More details concerning these tests are reported in Ref 177, 188, and 189.

For 1050-O, the experimental shear stress/shear strain curves along the two shear directions showed that the material exhibits anisotropic strain hardening (Fig. 16). The strain hardening in the initial stage of plastic deformation is higher for simple shear in the TD (90°) but saturates prematurely compared to simple shear at 45° from the RD. For 6022-T4, this effect is also observed but much less pronounced. In previous work (Ref 23, 188, 189), two microstructural parameters were invoked to explain this phenomenon: dislocation cell structure and crystallographic texture. The pole figures were measured using standard x-ray diffraction techniques. The resulting (111) pole figures (Fig. 17) indicated that both as-received materi-

als exhibited a preponderant {100}<001> cube texture, although stronger in the 1050-O sheet sample than in the 6022-T4. As expected, the 1050-O sample developed a well-defined dislocation microstructure during deformation, principally dislocation walls on the (111) planes oriented near the planes of maximum shear stress. The 6022-T4 alloy also displayed a dislocation structure with similar features, but the walls were much fainter and the overall dislocation distribution was more uniform (Fig. 18).

**Simulations.** Two constitutive models, phenomenological and polycrystal, were implemented into the user material subroutines provided in FE commercial codes (Yld2004-18p yield function into MSC.Marc HYPELA2, MSC. Software Corp., and polycrystal model into ABAQUS UMAT, ABAQUS Inc.) and used for the simple shear test simulations. The meshes and boundary conditions for the shear tests are represented in Fig. 19. The left grip was fixed, while the right grip was allowed to move along the vertical direction only. The FE meshes were generated only for the shear deformation zone of the specimens (not the grip area), using 320 and 800 uniform elements for 1050-O and 6022-T4, respectively, with a single layer through the thickness direction (Fig. 19).

The input data and resulting Yld2004-18p coefficients (see the section “Anisotropic Yield Functions” in this article) for the 1050-O and 6022-T4 sheet samples are given in Tables 1 and 2, respectively. For the FE simulations performed with Yld2004-18p, isotropic hardening was assumed with the stress-strain relationships:

- 1050-O:  $\bar{\sigma} = K(\bar{\epsilon} + \bar{\epsilon}_0)^n$ ,  $K = 132$  MPa (19 ksi),  $\bar{\epsilon}_0 = 0.0005$ , and  $n = 0.285$
- 6022-T4:  $\bar{\sigma} = A - B \exp(-C\bar{\epsilon})$ ,  $A = 396$  MPa (57 ksi),  $B = 234$  MPa (34 ksi),  $C = 6.745$

as measured with the RD uniaxial tension and bulge tests, respectively.

**Fig. 18** Dislocation substructure developed during simple shear of aluminum alloy 1050-O and 6022-T4 sheet samples (for different amounts of shear strain:  $\epsilon_{12} = 0.5 \times \gamma$ ). Source: Ref 177

Figure 20 represents the effective stress contours for the shear specimens deformed up to a shear strain of  $\gamma/2 = 0.25$  for the 1050-O and 6022-T4 sheet samples. It was observed that the experimental and predicted shapes of the specimen ends were very similar. Moreover, the FE simulations indicated that, for the strain range investigated, the deformation in the shear specimens was quite uniform, that is, end effects were minimal. The shear stress/shear strain curves along the two shear directions (at 45° from RD and in the TD) for the 1050-O and 6022-T4 sheet samples as predicted with Yld2004-18p are given in Fig. 21. The results were found to be in good agreement with the experimental trends (Fig. 16). For 1050-O, although the material was assumed to exhibit isotropic hardening, the simulations were able to reproduce a certain amount of anisotropic hardening observed experimentally during simple shear. For 6022-T4, although the difference in hardening between the two test orientations was noticeable and consistent with the experiments, this effect was small. The influence of the element size was evaluated by performing simulations with only one element (1 by 1 by 0.1, unit: millimeters) for both materials. It was shown that the element size had only a negligible effect on the results (Fig. 21). Therefore, the simulations using crystal plasticity were performed with only one element.

For simulations using a rate-dependent crystal-plasticity model (see the section “Crystal-Plasticity Models” in this article), a

trial-and-error method was employed to find the hardening parameters that provided a good approximation of the uniaxial hardening curves (and biaxial curve for 6022-T4). The strain-rate sensitivity coefficient for 1050-O was set to 0.01, which corresponds to the experimental value. For 6022-T4, the strain-rate sensitivity coefficient was arbitrarily set to 0.001, because the experimental value for this type of material is usually close to zero or slightly negative. The textures corresponding to the (111) pole figures (Fig. 17), which include approximately 1000 grain orientations each, were used as input. The simple shear-hardening curves predicted with crystal plasticity are shown in Fig. 22 for both sheet samples. Again, the trends predicted with this model were in very good agreement with the experiments (Fig. 16). The relative shapes of the stress-strain curves predicted with crystal plasticity were similar to those predicted with the phenomenological model, but the strain-hardening difference was larger.

In summary, the simple shear stress-strain curves of 1050-O and 6022-T4 aluminum alloy sheet samples were predicted using FE analyses with two constitutive material descriptions. Although the constitutive coefficients were identified using uniaxial tension and bulge test stress-strain curves, the simple shear-hardening responses were in good agreement with the experiments. It was shown that, even for a material exhibiting an isotropic strain-hardening behavior, the simple shear behavior could display an apparent anisotropic strain-hardening behavior due to the combined effect of plastic anisotropy and realistic boundary conditions. Crystal plasticity, led to a real anisotropic-hardening effect resulting from crystallographic texture evolution. Both effects, apparent and real, could fully explain the behavior of 1050-O and 6022-T4 sheet samples in simple shear. It was also concluded that the apparent anisotropic hardening was due to texture but not to dislocation microstructure. More details can be found in Ref 177.

**Example 2: Finite Element Analysis of Cup Drawing.** Cup drawing is not only a material test but also a forming operation, which accounts for the combined effects of blankholder force, friction, and sheet bending/unbending. Drawing of a circular blank with a circular punch is one of the best benchmarks to evaluate planar anisotropy. After this operation, the wall-height profile around the periphery of the resulting cup is usually not constant but exhibits peaks (also called ears) and valleys. The objective of this example is to show how FE analysis can be used to describe cup drawing for a 2090-T3 alloy sheet, which exhibits more than four ears. The Yld2004-18p yield function (see section “Material Modeling” in this article, and Ref 42) was used for the description of the plastic behavior of the aluminum alloy sheet. The FE cup-height profile was computed and compared with the results of a simple but more time-efficient analytical model as well as with experimental results.

Using the isotropic-hardening assumption, there have been previous efforts to simulate anisotropic phenomena such as the formation of ears in drawing circular blanks for aluminum alloy sheets. For this purpose, Chung and Shah (Ref 190) and Yoon et al. (Ref 169), respectively,

applied the stress and the strain-rate potentials proposed by Barlat et al. (Ref 37, 51) for a 2008-T4 aluminum alloy sheet. Andersson et al. (Ref 191) employed the criterion by Karafillis and Boyce (Ref 38) for the limiting dome height test. Yoon et al. (Ref 192) used Yld96, the yield function suggested by Barlat et al. (Ref 193) for circular deep drawing of a 2090-T3 aluminum alloy sheet. Yoon et al. (Ref 44, 194) simulated a reverse cup-drawing test using Yld2000-2d (see the section “Anisotropic Yield Functions” in this article, and Ref 41). Recently, Yoon et al. (Ref 195) successfully predicted six and eight ears in a circular cup drawing using Yld2004-18p (Ref 42).

**Finite-Element-Based Earing Profile.** The input data used to determine the anisotropy coefficients of the 2090-T3 aluminum alloy sheet sample are given in Tables 3 and 4. Polycrystal calculations were used to determine the out-of-plane properties given in Table 3. The out-of-plane data consisted of uniaxial tension yield stresses obtained at 45° between the symmetry axes in the planes (RD, normal direction, or ND; RD) and (TD, ND), where ND is the normal direction of the sheet, and the simple shear yield stresses in these planes. Therefore, the 18 coefficients for the yield function were optimized using 20 input data. The Yld2004-18p coefficients (see the section “Anisotropic Yield Functions” in this article) are given in Table 5. It is worth noting that, if a crystal-plasticity model were not available or if a plane-stress shell model

was employed for Yld2004-18p, the assumption  $\alpha_7 = \alpha_8 = \alpha_{16} = \alpha_{17} = 1$  could be employed for the out-of-plane anisotropy coefficients. The stress-strain curve used for the simulation was given by the relationship  $\bar{\sigma} = 646(0.025 + \bar{\epsilon})^{0.227}$  (MPa). Figure 23 shows the yield surfaces of the 2090-T3 sheet sample predicted using Yld2004-18p. Figure 24 depicts the normalized yield stress and  $r$ -value anisotropies, calculated with Yld2004-18p and determined experimentally. In Fig. 24, the results of another yield function, denoted Yld96 (Ref 193), are included for comparison purposes. Yld2004-18p accounts for uniaxial properties measured every 15° in the plane of the sheet, whereas the other yield function accounts for tensile properties in only three directions. These figures show that Yld2004-18p accurately captures yield stress and  $r$ -value directionalities very well.

A sketch of the cup-drawing process that was simulated is shown in Fig. 25. The specific dimensions of the tooling and the process variables used in the simulations for the 2090-T3 sheet sample are as follows:

Punch diameter:	$D_p = 2R_p = 97.46$ mm (3.84 in.)
Punch profile radius:	$r_p = 12.70$ mm (0.50 in.)
Die opening diameter:	$D_d = 2R_d = 101.48$ mm (4.00 in.)
Die-profile radius:	$r_d = 12.70$ mm (0.50 in.)
Blank radius:	$D_b = 2R_b = 158.76$ mm (6.26 in.)
Initial sheet thickness:	1.6 mm (0.06 in.)
Coulomb coefficient of friction:	0.1
Blankholding force:	22.2 kN (2.5 tonf)

The blankholding force was selected to provide a pressure of approximately 1% of the yield stress in order to prevent wrinkling. The friction coefficient was chosen as a typical value for a well-lubricated interface between the sheet and the blankholder. Only a quarter section of the cup with the associated symmetry boundary conditions was analyzed in light of the orthotropic material symmetry. A total of 340 solid elements and 747 nodes with one layer of elements through the sheet thickness were used for the simulation. A user-material subroutine combined with MSC.Marc was employed, based on an implicit time-integration scheme. The Newton-Raphson residual norm of 0.0001 was chosen in the FE simulations for the

convergence criterion. Approximately 2 h were required to complete the FE cup-drawing analysis using an HP 730 computer (Hewlett-Packard Co.).

Figure 26 shows the deformed configurations of the completely drawn cups. The results obtained with Yld96 are included for comparison purposes. It can be seen that Yld96 predicts four ears, while Yld2004-18p predicts six. In Fig. 27, measured and predicted cup-height profiles (also called earring profiles) are compared for the 2090-T3 sheet sample. For an orthotropic material, the cup-height profile between 0 and 90° should be a mirror image of the cup-height profile between 90 and 180° with respect to the 90° axis. However, the measured earring profile slightly deviates from this condition. This deviation may have occurred because the center of the blank was not aligned properly with the centers of the die and the punch during the drawing experiment. Generally, this plot shows that the earring profile obtained from the present theory is in very good agree-

ment with the measured 2profile. In particular, the small ears around 0° (or 360°) and 180° are well predicted.

In summary, this example indicates that an appropriate phenomenological yield function can be used in the FE simulation of the drawing process to predict an earring profile in good agreement with the experimental profile, even for a cup exhibiting more than four ears. In order to obtain this type of accuracy, the anisotropy of the tensile properties must be described very accurately. In the present case,  $r$ -values and flow stresses were determined with tensile tests conducted every 15° in the plane of the sheet and were very well captured with the yield function Yld2004-18p.

**Analytical Earring Profile.** Sometimes, for a quick assessment, it is advantageous to use a simple analytic equation to predict the earring profile. For this purpose, the blank of a cup is viewed as a ring (Fig. 28), the inner edge of which is drawn into the inside cavity under uniform displacement boundary control. When the ring starts to draw in, different levels of compressive strains are generated circumferentially due to planar anisotropy. The corresponding radial strains, contributing to the cup-height profile (earring profile), result from the incompressibility condition under a plane-stress state.

From Fig. 28, it is clear that the behavior of the ring in the rolling direction is controlled by the property of the material in compression in the transverse direction. Generalizing, the behavior of the ring in the direction defined by  $\theta$  is controlled by the property of the material in compression in the direction defined by  $\theta + 90^\circ$ . Assuming that, for a given direction, uniaxial tension and compression lead to identical properties, the  $r$ -value directionality can provide a reasonable approximation of the strains at the rim of the ring (Ref 180).

**Fig. 24** Measured and calculated variations of the normalized yield stress and  $r$ -value as a function of the angle between rolling and tensile direction for aluminum alloy 2090-T3. Source: Ref 195

**Fig. 26** Finite element predictions of the completely drawn cups for aluminum alloy 2090-T3 using (a) Yld96 and (b) Yld2004-18p yield functions

For the completely drawn cup (Fig. 29), it is assumed that no deformation of the sheet occurs at the flat punch head. Hence, the wall deformation can be mapped with the deformation of the flange, leading to an expression for the total cup height as a function of the parameter  $\theta$  (Ref 194):

$$H_\theta = r_p + (R_b - R_c) + \frac{r_{\theta+90}}{(r_{\theta+90} + 1)} \times \left( (R_c - R_b) + R_b \ln \left( \frac{R_b}{R_c} \right) \right) \quad (\text{Eq 74})$$

where  $R_c$  is given by  $R_c = (R_p + R_d)/2$ . The parameter  $\theta$  describes the angle (in degrees) between the position of the rim considered and the rolling direction. Equation 74 was derived based on a midplane geometry by neglecting the sheet thickness. Using this equation, it is possible to calculate the approximate cup height from the initial blank size, cup geometry and  $r$ -value directionality.

The analytical prediction  $H_\theta$  (Fig. 27) leads to six ears, in agreement with the FE simulation results obtained with Yld2004-18p and the experimental data. It is also worth mentioning that the resulting cup-height profiles exhibit a number of peaks and valleys equal to the number

**Fig. 27** Comparison of measured earring profiles for deep-drawn cups of aluminum alloy 2090-T3 with predictions from finite element simulations (using two different yield functions) and an analytical model. Source: Ref 195

**Fig. 28** Illustration of the compressive stresses developing in the elements at the rim of circular blank drawn into a circular cup. TD, transverse direction; RD, rolling direction

of maxima and minima of the  $r$ -value directionality (Fig. 24). More precisely, peaks and valleys as defined by the angle  $\theta$  in the earring profile correspond to maxima and minima, respectively, in the  $r$ -value directionality expressed as a function of  $\theta + 90^\circ$ . Although additional verifications are needed, these results suggest that, for a given material, the relative earring profile and  $r$ -value directionality are “mirror images” of each other with respect to the transverse direction.

**Example 3: Finite Element Simulation of Reverse Cup Drawing.** Reverse cup drawing, proposed as a benchmark example at the NUMISHEET '99 conference (Ref 196) illustrates the importance of the yield function for accurate FE modeling simulations. In this process, plastic anisotropy, friction, and sheet bending/unbending are all relevant parameters. Simulation results were compared with data available from the conference proceedings (Ref 196).

The workpiece material was an aluminum alloy 6016-T4 sheet sample. The stress-strain curve and yield surfaces were described by the Swift law and the Yld2000-2d yield function (Ref 41), respectively. Because the biaxial yield stress was not available for this material, the assumption  $\sigma_b = \sigma_0$  was employed, based on

the properties of similar materials. The eight coefficients of Yld2000-2d were obtained with seven input data using the practical assumption  $c_{12}'' = c_{21}'' = 0$  (see the section “Anisotropic Yield Functions” in this article). Tables 6 to 8 list the different data and coefficients used for this material. For this 6016-T4 sheet sample, an excellent agreement was observed between experimental and calculated (Yld2000-2d) variations of the  $r$ -value and the flow stress as a function of the angle between rolling and tension direction (Fig. 30). For comparison purposes, the amplitude of the flow stress anisotropy predicted with Hill’s 1948 yield function, also represented in Fig. 30, is largely overestimated. This is because with this classical yield function, the anisotropy coefficients are calculated with the  $r$ -values only as input, not the flow stresses.

The specific dimensions of the tools are given in the NUMISHEET '99 proceedings (Ref 196). Only a quarter section of the cup was analyzed in light of the orthotropic material symmetry. Figure 31 shows the FE mesh used for the analysis; it comprised 1050 continuum-based shell elements (Ref 161). The process variables were as follows:

Initial sheet thickness:	1.15 mm (0.045 in.)
Coulomb coefficient of friction:	0.1
Gap between blankholder and die:	2.0 mm (0.08 in.)

The cup-drawing simulation was performed assuming isotropic hardening; that is, the yield-function coefficients were kept constant during deformation. It took 120 and 180 steps to translate the punch 60 mm (2.4 in.) in the forward and 80 mm (3.2 in.) in the reverse directions, respectively.

**Experimental Validation.** Figure 32 shows the deformed cups at intermediate and final stages of the forward and reverse drawing steps. Figure 33 shows that the predicted load-displacement curves agree qualitatively with the experimental curves, although the simulated results underestimate the measured loads. This can probably be attributed to the lack of transverse shear stress in the general thin-shell formulation. Figures 34(a) and (b) show the predicted and experimental thickness-strain distributions measured along the rolling and diagonal ( $45^\circ$  from RD) directions, respectively, after the forward and reverse drawing operations. Although the simulated thickness in the flange area in the diagonal direction is slightly

**Fig. 31** Initial finite element mesh of the circular blank

overestimated, the agreement between predictions and measurements is generally excellent. The overestimation in the diagonal direction is presumably due to the thin-shell formulation without half-thickness consideration of the sheet material.

Nevertheless, this example shows that the material description with Yld2000-2d was able to capture experimental results very well despite the assumption of isotropic hardening, in particular, the different strain profiles in the two directions (rolling and diagonal) investigated. Moreover, separate simulations using the more classical yield function proposed by Hill (Ref 35) could not be completed because of convergence issues. It is believed that these problems were

due to the anisotropy of the sheet, which, as suggested by Fig. 30, was largely overestimated using the more classical yield function. This anisotropy was thought to be responsible for locally excessive blankholder force and element distortion, leading, in turn, to a numerical instability.

**Example 4: Modeling of Wrinkling During Cup Drawing.** Finite element analysis has also been applied to analyze wrinkling during cup

drawing. For this example, the dimensions of the tooling are as follows:

Punch diameter:	$D_p = 85 \text{ mm (3.3 in.)}$
Punch-profile radius:	$r_p = 7 \text{ mm (0.28 in.)}$
Die opening diameter:	$D_d = 88 \text{ mm (3.5 in.)}$
Die-profile radius:	$r_d = 8 \text{ mm (0.32 in.)}$

The FE analyses were carried out using the Yld91 (Ref 37) planar anisotropic material model (a particular case of Yld2004-18p). One-half of the circular blank was discretized into 2100 elements (30 elements in the radial direction and 70 elements in the circumferential direction) and 2201 nodes (Fig. 35). The wrinkling behavior was described using the bifurcation algorithm mentioned in the section "Compressive Instability" in this article. The process parameters and material constants used in the analysis are listed in Table 9.

Finite element analyses and experiments were carried out to determine the onset of wrinkling and the number of wrinkles for various values of the blankholding force. Figure 36 shows the measured and computed configurations of the cup after partial drawing. The experiments were carried out three times for each value of the blankholding force. When this force was set to 2 kN (0.22 tonf), 14 wrinkles resulted from the FE analysis, while 9, 11, and 12 wrinkles were

Table 9 Material constants and friction coefficient for cylindrical cup drawing

Process parameters/material constants	Values
Material	Al 6111-T4
Initial blank thickness	0.9144 mm (0.036 in.)
Coulomb friction coefficient	0.1
Yield stress	185.92 MPa (26.96 ksi)
Young's modulus ( $E$ )	69 GPa ( $10 \times 10^6$ psi)
Poisson's ratio	0.33
Stress-strain curve	$\bar{\sigma} = 454.8 - 268.8 \exp(-6.45\bar{\epsilon})$
$r$ -value	$r_0 = 0.83, r_{45} = 0.86, r_{90} = 1.42, \bar{r} = 0.99$
Anisotropic coefficients for Barlat's yield (Ref 37)	$c_1 = 1.0406, c_2 = 0.9582, c_3 = 0.9962, c_4 = c_5 = c_6 = 0.9071, a = 8.0$

Fig. 35 Mesh used in the analysis of wrinkling and the definition of characteristic lengths

observed experimentally. When the blankholding force was equal to 5 kN (0.56 tonf), 22 wrinkles were predicted, and 17, 18, and 19 were measured. Finally, for a blankholding force of 8 kN (0.90 tonf), the predicted wrinkle number was 32, while the experimental numbers were 24, 27, and 28. The number of wrinkles obtained from the FE analyses were in reasonable agreement with the experimental results. Moreover, the larger number of wrinkles measured on the

cups drawn with a higher blankholding force was well captured by the model.

Figure 37(a) shows the critical punch stroke at which wrinkling grew abruptly, and Fig. 37(b) shows the normalized wrinkle wavelength. In Fig. 37(a), it is shown that the load corresponding to the onset of wrinkling was overestimated by the FE analyses and that the onset and growth of wrinkles was retarded as the blankholding force increased. It is thought that initial imperfections, such as eccentricity of the circular blank with the tool and the nonflatness of the initial blank, may have accelerated the initiation of wrinkling. With the application of grease as a lubricant, a lower force may have led to a larger gap between the blank and blankholder, which could have resulted in imperfections with higher initial amplitudes. Figure 37(b) shows that the normalized wrinkling wavelength decreased (more wrinkles) as the blankholding force increased. This is because, as the blankholding force increased, the lower bifurcation mode was constrained, and wrinkling took place in a higher bifurcation mode. It was also shown in Fig. 37(b) that the number of wrinkles is overestimated (wrinkling wavelength underestimated) by the FE analysis, which is also thought to be due to the effects of imperfections.

Figure 38 shows the normalized critical wrinkling stress for various blankholding forces, which was obtained by averaging the circumferential stress of the edge elements for the

punch stroke at which wrinkling grew abruptly. As can be expected, the critical wrinkling stress increased as the blankholding force increased. Considering the difficulty and sensitivity of all contributing parameters in the modeling of wrinkling, the predictions of the FE analysis are considered to be in very good agreement with the experimental results. This shows that the FE analysis, combined with a bifurcation algorithm, can be used reliably for the analysis of wrinkle initiation and growth in sheet metal forming processes.

**Material and Friction Effects.** Material properties such as strain-hardening rate and plastic anisotropy can have an effect on the wrinkling behavior of sheet metal. In order to investigate this effect, the initiation and growth of wrinkles in the cylindrical cup-drawing process were computed with the Swift hardening law and Hill's 1948 yield function, assuming planar isotropy (in-plane properties are the same; also called normal anisotropy). Figure 39 shows the simulated critical punch stroke at which wrinkling initiates for various values of the normal anisotropy coefficient,  $r$ , and of the strain-hardening exponent,  $n$ . In Fig. 39(a), wrinkling initiation occurred at higher punch strokes (loads) as the value of the anisotropy coefficient increased, and it disappeared when this coefficient reached a value of 2.0. Examination of the yield surface shows that the material can flow plastically with a lower pure shear stress ( $\sigma_s$ ) in the flange when the anisotropy parameter  $r$  is higher. This means that a lower in-plane compressive stress ( $\sigma = -\sigma_s$ ) is needed to deform the material, thus postponing wrinkling to higher loads. Figure 39(b) shows that increasing values of the strain-hardening exponent delayed the onset of wrinkling. Moreover, strain-hardening exponents of 0.25 and 0.3 inhibited the occurrence of wrinkling. This result appears to be reasonable, because a higher strain-hardening exponent leads to a larger elastoplastic modulus. All these simulation results were consistent with the experiments of Narayanasamy and Sowerby (Ref 197), who showed that sheets with higher normal anisotropy and strain-hardening rate resist wrinkling better.

Finite element simulations were also carried out with the Yld91 yield function (Ref 37) in order to assess the influence of planar anisotropy (different in-plane properties) on the wrinkling behavior. The anisotropy coefficients used in this investigation are listed in Table 9. A blankholding force of 3 kN (0.34 tonf) was imposed. Figures 40(a) and (b) show the deformed configurations analyzed with normal anisotropy (Hill's 1948) and planar (Yld91) anisotropy, respectively. For normal anisotropy, wrinkling was predicted to occur at a punch stroke of 25 mm (1.0 in.), and the number of wrinkles was 20. For planar anisotropy, however, the compressive instability initiated at a punch stroke of 20 mm (0.8 in.) and produced 18 wrinkles. This effect was explained by the thickness in the flange, which is no longer uniform due to planar anisotropy. This nonuniformity could induce

imperfections and modify the susceptibility to wrinkling. However, the comparison between these two simulations is not rigorous because, in addition to the two types of anisotropy (normal and planar), two yield functions were used. The difference in wrinkle number could also be influenced by the generally higher shear yield stress of Hill's 1948 yield function compared to Yld91.

Finite element analyses were performed under constant blankholder force (BHF) with various values of the Coulomb friction coefficient. The corresponding deformed configurations are shown in Fig. 41. When the friction coefficient increased, the number of wrinkles decreased, and when this coefficient reached a value of 0.2, tearing took place instead of wrinkling. Figure 42 shows the number of wrinkles, the critical punch

stroke at which wrinkling grows abruptly, and the edge draw-in for various values of the friction coefficient. It was shown that if wrinkling initiates a higher punch stroke, the number of wrinkles decreases. This is due to the fact that edge draw-in decreases because of the higher friction force, and therefore, lower compressive circumferential stress is induced.

**Example 5: Finite Element Simulation of Hemming Operations.** Hemming is a process used in the automotive industry to join inner and outer skins of components such as hoods, doors and deck lids. Hemming is a 180° bending operation conducted in three steps: a bending or flanging step, followed by prehemming and final hemming steps. Parameters such as the die radius, the flange radius and length, and the prehemming punch travel influence the final

product quality. Typical Al-Mg-Si 6XXX-T4 sheet processed by conventional means usually produces acceptable relieved flat hem ratings.

In this example, a specific 6XXX-T4 alloy sheet exhibited successful flat hemming when the hem line was aligned with the rolling

(d) EXP, BHF = 5 kN (0.56 tonf), stroke = 20 mm (0.8 in.). (e) FE, BHF = 8 kN (0.90 tonf), stroke = 40 mm (1.6 in.). (f) EXP, BHF = 8 kN (0.90 tonf), Exp, stroke = 35 mm (1.4 in.). Source: Ref 103

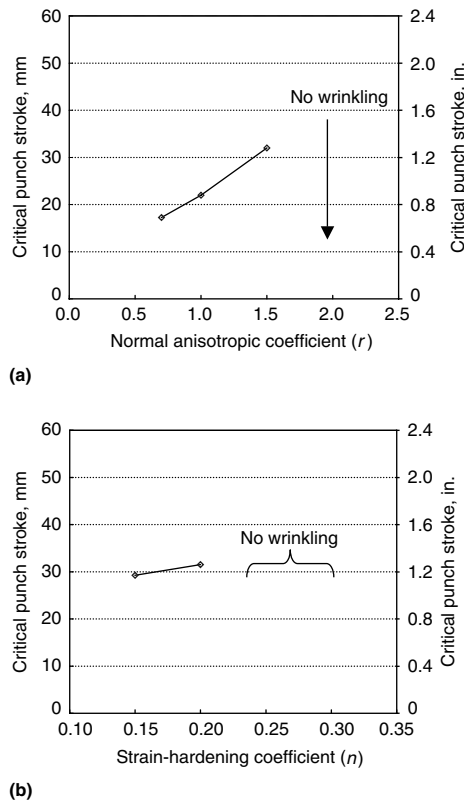

direction (RD-oriented hem). However, when the hem line was aligned with the transverse direction (TD-oriented hem), unacceptable hem ratings, that is, with some amount of cracking, could be observed. Because of mechanical

fibering, it is counterintuitive that the RD-oriented hem leads to a better performance than the TD-oriented hem.

It is known that the stress level affects shear localization and cracking, everything else being constant. Therefore, these analyses pointed to the influence of the stress on fracture during hemming. The stress state that is prominent in hemming corresponds to plane strain, characterized by the major component  $\sigma_p$ . The relevant values of this stress component are associated with the RD and TD directions for the

two specific cases of TD- and RD-oriented hemming, respectively. These stresses can be evaluated relative to the RD tensile yield stress,  $\sigma_y$ , using the yield surface concept. The plane-strain yield stress is a function of the anisotropy ratio  $H = \sigma_p/\sigma_y$ , which depends on the yield-surface shape and consequently on crystallographic texture. Therefore, texture analyses and crystal-plasticity yield-surface calculations were conducted for typical and experimental 6XXX-T4 sheet samples. The results showed that, in general, the yield surface was distorted (anisotropic) and that the RD plane-strain yield stress,  $\sigma_p^{RD}$ , was higher than the TD plane-strain yield stress,  $\sigma_p^{TD}$ , particularly for the experimental material. This may explain why RD-oriented hemming was acceptable (lower  $\sigma_p^{TD}$ ) and TD-oriented hemming was more prone to fracture ( $\sigma_p^{RD}$  much higher) for the experimental material. Because it is usually desired to maximize  $\sigma_y$  for product applications, the other control parameter,  $H$ , can be modified to reduce the plane-strain yield stress. In this particular example, texture analyses and crystal-plasticity models can be used to define the appropriate texture and provide information for alloy processing. This aspect is not covered here, but the simulation of the hemming process is.

*Finite element simulations* of the hemming process were carried out for the 6XXX-T4 sheet sample in the RD and TD orientations using the Yld2004-18p yield function to account for plastic anisotropy. The material data for the conventionally processed alloy are shown in Ref 198. Figure 43 summarizes the results. This figure shows that the maximum plastic strain computed in the bent area is approximately the same for all specimens but one, that is, the TD-oriented hem specimen for the experimental alloy. This is in good agreement with observations, because this specimen only exhibits cracks on the hem line. Figure 44 shows a close-up view of one of the simulated hem specimens. It shows that the maximum strain is not located at  $90^\circ$  with respect to the plane of the sheet but in a location that agrees well with experimental observations of the cracking zone.

**Fig. 45** Forming tool setup for an automotive underbody cross-member panel

**Example 6: Finite Element Simulation of Automotive Panel Stamping.** Finite element analysis can be applied to the more complex forming problems encountered in industry. The present example deals with the application of FE analysis to the stamping of an automotive component. The final shape of an underbody cross-member panel results from three major steps: forming, trimming/piercing, and springback. In this example, the final shape of the part is particularly dominated by the effect of springback. The lower punch, binder, and upper die used during forming are illustrated in Fig. 45. This tooling geometry had a  $x$ - $z$  plane of symmetry at  $y = 0$ . A 5182-O aluminum alloy sheet, 1.6 mm (0.06 in.) thick, was used as a blank material. In order to characterize the material with Yld2000-2d and Yld2004-18p yield functions (see the section “Anisotropic Yield Functions” in this article), tensile tests conducted in different directions from rolling, with angles in  $15^\circ$  steps, as well as bulge and disk-compression tests were performed. Figure 46 shows that the experimental  $r$ -value and flow-stress directionalities are very well captured Yld2000-2d and Yld2004-18p yield functions.

The process parameters used in the forming simulation were as follows:

Total blankholder force:	400 kN (45 tonf)
Binder travel:	100 mm (4 in.)
Tool moving direction	
Upper die:	Moving in the $-z$ -direction
Binder:	Moving in the $-z$ -direction

In the forming simulation, the maximum downward velocity of the upper die was limited

**Fig. 46** Normalized flow stress and  $r$ -value experimentally measured and calculated using Yld2000-2d and Yld2004-18p yield functions as a function of the angle of the rolling and tensile directions for an aluminum alloy 5182-O sheet sample

to 5 m/s (16 ft/s). The initial setup positions and physical dimensions of the draw beads were well described in the benchmark specifications (Ref 198). In the present forming simulation, line beads were used. The initial blank was modeled with coarse meshes (3124 shell elements). During the forming simulation, two-level adaptive mesh refinement was applied, and the final number of elements after forming was 27,610. Figure 47 shows that the plastic strain contours predicted with Yld2000-2d and Yld2004-18p are almost coincident. The reason is that, as suggested in Fig. 46, both yield functions predict the same plastic behavior. The calculations based on Yld2000-2d and Yld2004-18p took approximately 3 and 13 h, respectively.

Figure 48 shows the sections used for the draw-in measurements ( $d_1$ ,  $d_2$ , etc.). In this simulation, a penalty method was used to enforce the contact conditions. The use of a very large penalty coefficient could cause partial contact of the left lower corner of the part, because of the coarseness of the mesh. This partial contact could result in very inaccurate draw-in. In order to establish the whole contact of the sheet under the binder, an appropriate penalty coefficient should be used. In this work, a finer mesh was used, which drastically reduced the influence of the penalty parameter. Table 10 shows that the amounts of draw-in predicted by the FE simulation were in good agreement with the measurements, even though the simulation used a line-bead approach.

After forming, trimming and piercing were simulated with the aid of the IGES line data (a given international standard for surface file format). Figure 49 shows the step-by-step procedure. All the state variables were mapped without any changes during the trimming and piercing processes.

**Springback.** The boundary conditions for the springback analysis of the underbody cross-member panel are shown in Fig. 50. In addition to the  $x$ - $z$  plane of symmetry, boundary conditions were applied at two points (“A” and “B”) in

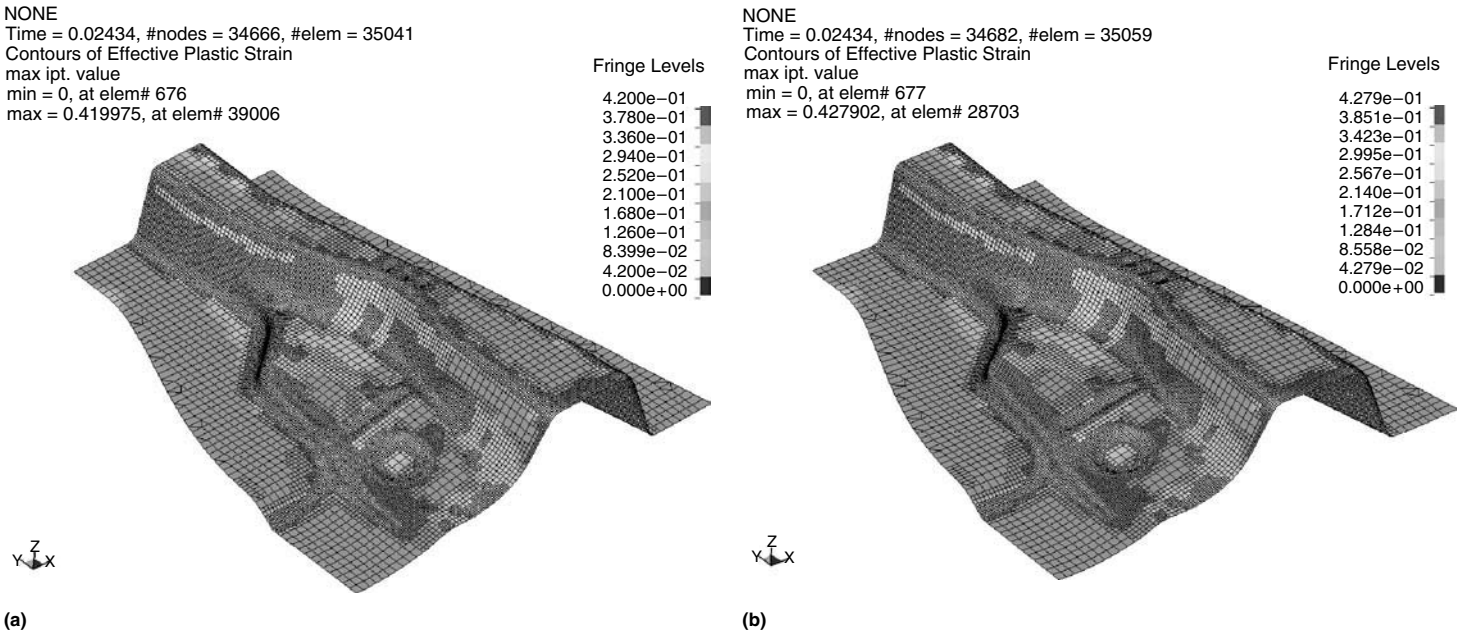

Fig. 47 Effective strain contours predicted using (a) Yld2000-2d and (b) Yld2004-18p. The maximum effective strain for each was 0.42

Fig. 48 Measurements of draw-in at sections I, II, and III of the automotive underbody cross-member panel

order to eliminate any rigid body motion. Figures 51 and 52 show the predicted displacement magnitude and the effective stress contour before and after springback, respectively. It can be observed that the effective stress level is higher before than that after springback. This means that springback occurs in a direction that minimizes the residual stresses. The predicted amounts of draw-in and the profiles of specific sections of the panel (Fig. 53: section I,  $y = 0$ , and section IV,  $y = -370$ ) after springback were compared with experimental results. Figure 54(a) shows that the prescribed profile obtained from the present simulation for section I was in excellent agreement with the experiment. In particular, the curled shape of the right wall was well predicted. Figure 54(b) shows the comparison between experiment and simulation results of section IV. The lifting of the left part and curling of the right wall were very well captured by the simulation and the predicted profile was in excellent quantitative agreement with the experiment.

Table 10 Blank draw-in amount at various locations after forming (Fig. 48)  
Measured in mm (in.)

Method	Draw-in location					
	d1	d2	d3	d4	d5	d6
Experiment	62.17 (2.45)	52.8 (2.08)	56.67 (2.23)	73.7 (2.90)	57.2 (2.25)	47.8 (1.88)
Simulation	60.0 (2.36)	50.7 (2.00)	56.9 (2.24)	73.5 (2.90)	57.7 (2.27)	50.5 (1.99)

**Example 7: Finite Element Modeling of Tube Hydroforming Processes.** Hydroforming has been an important sheet metal forming processes since it was developed before World War II for application to the German aircraft industry (Ref 199). Approximately 30 years ago, hydroformed parts were fabricated by expanding straight or prebent tubes to manufacture manifold elements and components for sanitary use. Hydroforming offers several advantages compared to conventional manufacturing via stamping and welding (Ref 200), in particular, part consolidation and tooling cost. Moreover, while saving on material and manufacturing costs, hydroforming allows the production of parts with improved performances, such as weight, strength, and stiffness, compared to conventionally processed parts in a variety of applications (Ref 201). Today (2006), many hydroformed products, including exhaust manifolds, engine cradles, exhaust pipes, space frames, and so on, are mass-produced in the automotive industry (Ref 202, 203).

Tube hydroforming is a complex process, and it is essential to understand the basic technology to take advantage of the inherent formability of the material. In this process, while the tube is pressurized, axial forces are applied to its ends in order to overcome frictional effects, which cause

premature failure by strain localization. However, if the axial forces are too large, buckling or wrinkling can occur. Consequently, a proper combination of internal pressure and axial compressive force is important to prevent necking (therefore, tearing) as well as buckling. In addition to these process parameters, it is necessary to understand the influence of the tooling geometry, lubrication, and material behavior. Designing die and preform shapes, especially in the early stage, is one of the most difficult tasks. Optimal design is essential to produce final products without defects and to effectively reduce production time.

Recently, FE analyses were applied to the design of the tube hydroforming forming process. Guan (Ref 204), Kridili et al. (Ref 205), and Koc and Altan (Ref 206) simulated axisymmetric tube bulging, while Hwang and Altan (Ref 207) simulated the crushing performance of circular tubes into folds with an overall triangular cross section. Koc et al. (Ref 208) predicted the protrusion height of T-shaped parts using a three-dimensional FE analysis. Because a prebending process often precedes hydroforming, it is important to take into account the deformation during prebending in the simulations. Using FE analyses, some researchers have investigated the cross-sectional

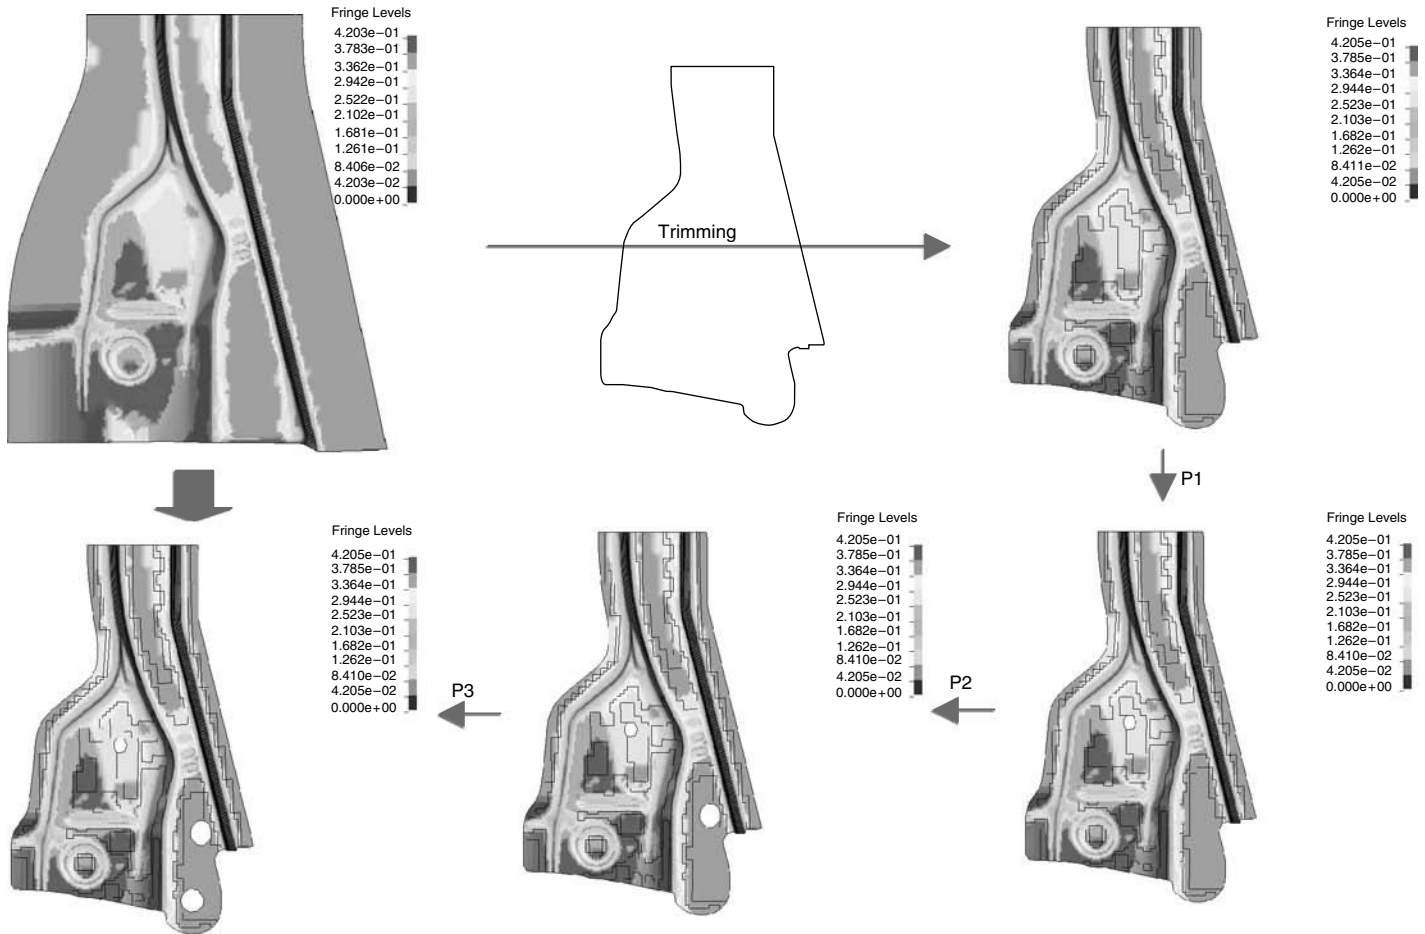

Fig. 49 Trimming and piercing procedure for the automotive underbody cross-member panel

Fig. 51 Predicted displacement magnitude after springback of the automotive underbody cross-member panel

shape change and wall thinning during prebending and integrated the results in subsequent hydroforming simulations (Ref 209–211). Yang et al. (Ref 212) further included springback after the prebending operation. Berg et al. (Ref 213) developed a numerical scheme to overcome problems due to concave cross-sections introduced by local buckling during prebending and preforming processes. For the optimization

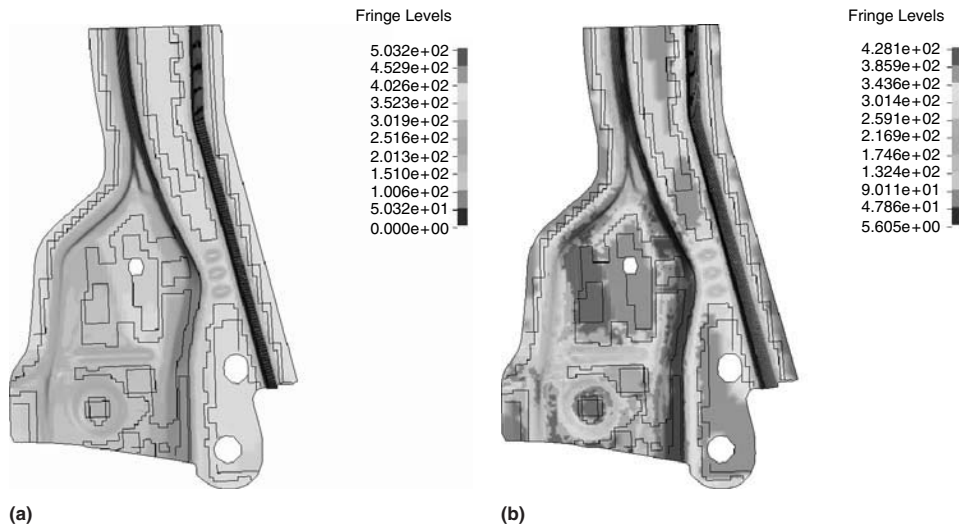

of the tube hydroforming in the design stage, several schemes based on FE analyses have been introduced (Ref 214–216). Chung and Yoon (Ref 217) applied a direct FE method (FE design) based on the ideal forming theory (see

the section “Ideal Forming Design Theory” in this article) to design the preform for tube hydroforming.

**Preform Design.** The use of the ideal forming theory for the optimal design of preforms is illustrated on two industrial hydroformed parts. The examples illustrate how the cross-sectional shape and the tube length can be optimized. Assuming that the final geometry is specified and, as a constraint, the initial thickness of the tube is imposed, an optimal straight, hollow preform (before bending) is determined from this design theory.

In the two examples, the isotropic strain-rate potential  $Srp93$  (Ref 51, 52, as well as the section “Strain-Rate Potentials” in this article) was used to describe the material plasticity, with the exponent set to the recommended value of  $b = 4/3$  for aluminum alloys. The stress-strain curve was approximated by the Swift law with the following parameters  $\bar{\sigma} = 359.8(0.001 + \bar{\epsilon})^{0.223}$  MPa.

For the first example, the uniform thickness of the tube preforms was assumed to be equal to 2 mm (0.08 in.). The final part shape after hydroforming is shown in Fig. 55. Only a half-section was considered in the simulation in

**Fig. 52** Predicted effective stress contour (a) before and (b) after springback of the automotive underbody cross-member panel

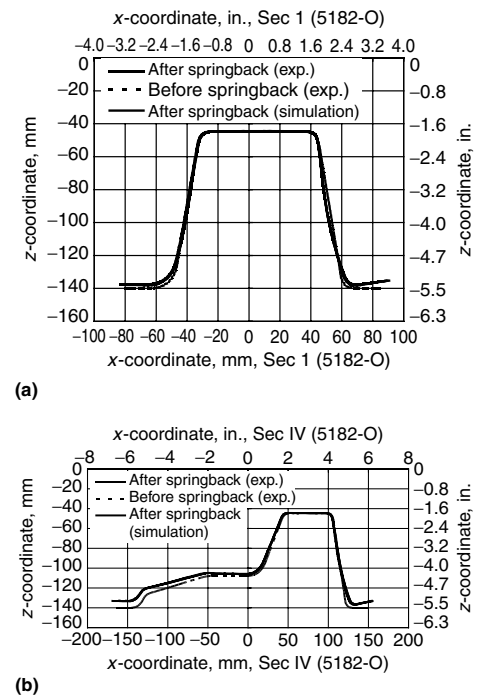

**Fig. 53** Definition of sections I and IV of the automotive underbody cross-member panel

view of the part symmetry. Because the solution is the result of a one-step procedure, it took only 2 min to complete the calculation of the initial preform shape. The ideal forming design code showed that the amount of optimal end feeding was 3.3 mm (0.13 in.), with an average pressure of 60.8 MPa (8.8 ksi), while the experimental feeding and pressure were 3.7 mm (0.15 in.) and 75 MPa (10.9 ksi), respectively, to successfully manufacture the final part. Figure 56 compares the thickness strains predicted with friction coefficients of 0.15 and 0.0 (no friction). This figure shows that when the

frictional effect is incorporated, more thinning is observed.

In the second example, the part geometry shown in Fig. 57 was considered. Figure 58 represents the predicted optimal preform tube calculated with the ideal forming code, neglecting the influence of friction. The results showed that the optimal cross section was not circular but close to an ellipse. The predicted thickness strain contours, which are also an output of the model, are plotted on the final part geometry in Fig. 57.

These two examples illustrate that the ideal forming code can provide useful information in

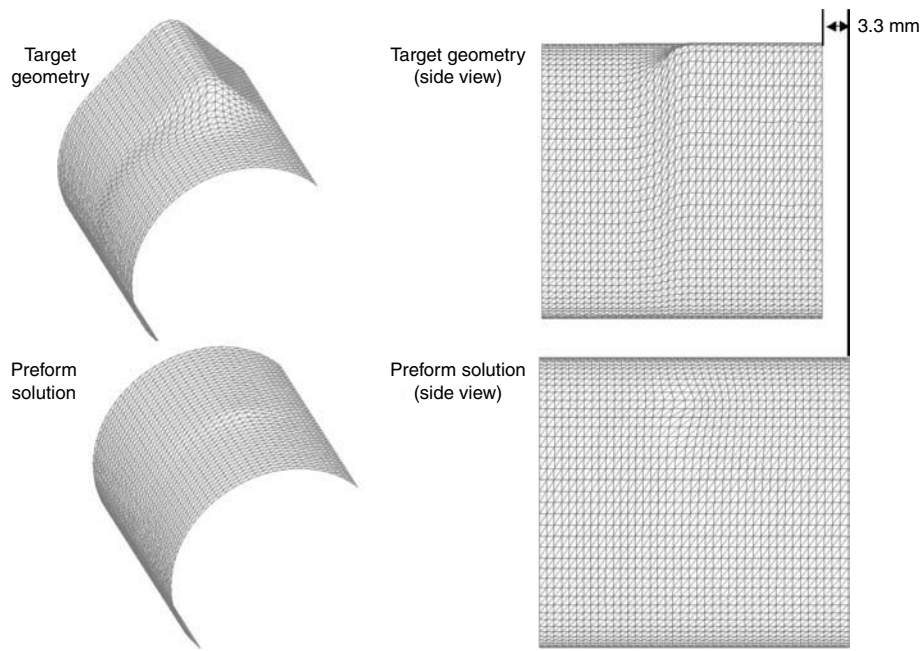

**Fig. 54** Profiles of automotive underbody cross-member panels at (a) section I and (b) section IV for 5182-O sheet sample. Experimental and predicted profiles after springback are almost coincident.

the early stage of design, which ultimately reduces the number of FE iterations required to finalize the design of a forming process.

**Example 8: Finite Element Simulations in the Design of a Beverage Can End.** In the rigid-packaging industry, products with smaller cut-edges and reduced design characteristics have been proposed to decrease overall product costs. However, for beverage can applications, clam-shell failures, as shown in Fig. 59(a), are often observed for many of the newly proposed end designs. Thus, a new geometric design that further increases the buckle pressure without clam-shell failure is an important and critical issue. In this example, finite element (FE) simulations were conducted to predict the resistance to clam-shell buckling and failure in the context of a Taguchi design approach (Ref 1). A plane stress yield function (Yld2000-2d; Ref 41), which accurately describes the behavior of aluminum alloy sheet was employed to model plastic anisotropy (see Fig. 7). The criterion for clam-shell failure was the forming limit curve (FLC) discussed in the section “Tensile Instability” in this article. Once the failure shape was properly predicted, the Taguchi method was used to extract the most important factors from the many possible design variables and to evaluate their influence on the initial buckle pressure. Finally, a new optimum design was proposed to improve the buckle pressure without clam-shell failure.

**Buckle Pressure Calculation.** In order to predict the buckle pressure, the center displacement

**Fig. 58** Predicted optimal preform tube with near-elliptical cross section. Source: Ref 217

of the shell was obtained from FE simulations. Figure 60 shows a schematic illustration of the shell center displacement as a function of pressure at several stages. The displacement at the center increases gradually at the early stage of pressurization. After this transient period (at the end of which the clam-shell initiates), the displacement increases abruptly. The pressure associated to this rapid change is defined as the critical buckle pressure and corresponds to the intersection of the two tangent lines in Fig. 60. Figure 59 compares the observed and simulated deformed shapes of the can end, which are in excellent agreement.

**Design Optimization.** After confirming the applicability of the FE simulation approach, a number of numerical simulations were conducted instead of experiments to optimize the design parameters in an efficient way. Eight among the twelve geometrical parameters shown in Fig. 61 were selected as variables (denoted A to H in Table 11) to design the best geometry allowing an increase of the buckle pressure. An  $L_{18}$  orthogonal array (Ref 1, 218) was constructed to define a set of 18 simulations (Table 11), which were used to evaluate the influence of each of the eight selected design parameters on the buckle pressure (Fig. 62). By this means, Parameter G was found to be most critical factor influencing the buckle pressure.

Further work was conducted in investigate in more detail the influence of this parameter and other conditions. Using the FE simulations, it was found that a buckle pressure of  $p_{\text{final}} = 0.64$  MPa could be obtained by judicious choice of the design geometry. This pressure was 0.07 MPa (11%) higher than the maximum pressure obtained with the original can end design. Moreover, the new design led to reduction of the maximum effective strain from 0.56 to 0.19, preventing the occurrence of clam-shell failure. Figure 63 shows the simulated and experimental deformed shapes based on the new design, which did not lead to clam-shell failure.

## Conclusions

The FE method applied to sheet metal forming process analysis and design, particularly for aluminum alloys, was briefly summarized in this article. Special emphasis was paid to the constitutive modeling and its implementation in FE codes. Tensile and compressive instabilities, which limit the formability of materials, as well as springback, which compromises the overall shape stability of a part, were analyzed. A few issues in the FE method, such as kinematics, element and matrix formulation, as well as stress-integration algorithms, were discussed. The ideal forming theory was briefly introduced as a direct method for the design of sheet-forming or hydroforming processes.

In this article, specific constitutive models suitable for aluminum alloy sheets (or thin tube) were presented. These models were always able

to capture experimental strain-hardening and plastic anisotropy features favorably. A variety of examples of sheet metal forming process simulations, such as cup-drawing, hemming, stamping, springback, hydroforming, and so on,

were given as illustrative examples. The simulation results were generally in excellent agreement with experimental measurements.

This overall theoretical approach illustrates the importance of material and process interac-

tions. In principle, modeling of sheet forming and microstructure evolution should be a concurrent process. However, in view of the size of the forming simulations and the complexity of the physical phenomena occurring during plastic deformation, it seems more efficient to use macroscopic constitutive models with one or more internal variables to account for the microstructure. Constitutive models at a finer scale are, of course, very important for the understanding of the microstructure evolution, for material design, and for providing a basis for the development of more advanced macroscopic models.

ACKNOWLEDGMENT

The authors are indebted to many of their colleagues, in particular from Alcoa Technical Center, Pittsburgh, Pennsylvania, whose contributions made this work possible. The authors also gratefully acknowledge Dr. Lee Semiatin from the US Air Force Research Laboratory, Wright-Patterson Air Force Base, Ohio, for his excellent review of the manuscript and his pertinent suggestions. Finally, the authors are obliged to ASM International personnel, in particular Mr. Steve Lampan, for the difficult task of preparing this article for publication.

# Statistical Analysis of Forming Processes

Stuart Keeler, Keeler Technologies LLC

STATISTICS are extremely important tools in the operation of press shops, providing numerical process analysis capabilities that far exceed the more traditional recording of simple breakage rates. During the past decades, the prime goal of metal forming was to make stampings to part print without breakage. Today, new requirements on product consistency have greatly increased the need for process analysis capabilities.

The most common use of statistics in the press shop is statistical process control (SPC). Although used in many formats, SPC is simply the use of statistical techniques such as control charts to analyze a process or its output and thus enable appropriate actions to be taken to achieve and maintain a state of statistical control. The use of SPC instead of traditional quality-control methods, such as inspection/sorting, is beneficial in a number of ways.

Statistical process control:

- Decreases scrap, rework, and inspection costs by controlling the process
- Decreases operating costs by optimizing the frequency of tool adjustments and tool changes
- Maximizes productivity by identifying and eliminating the causes of out-of-control conditions
- Allows the establishment of a predictable and consistent level of quality
- Eliminates or reduces the need for receiving inspection by the purchaser because it produces a more reliable, trouble-free product, resulting in increased customer satisfaction

The use of statistics in analysis of the forming process goes well beyond SPC. The whole area of design of experiments (DOE) is becoming important as the interactions within the forming process are detailed and studied. Many of the more difficult forming problems result from the interaction of two or more interactive variables. Identification of these interactive variables will not be accomplished by the traditional changing of one variable at a time. The argument has been made that conducting DOE tests in the press shop is nearly impossible because of the time and difficulty for sequential grinding and welding

of the tooling, securing metals with different properties, and implementing other process changes dictated by the DOE matrix. The rapid introduction of the computerized forming simulation into the press shop since early 2000 has made DOE studies an easy task. Extremely difficult changes for the press shop are only a few simple keystrokes on the computer.

This article discusses the role of statistics in sheet metal forming operations, both in terms of SPC techniques and design of experiments. However, most of the concepts are generic and can be applied to any metalworking process.

## The Forming Process

A wide range of forming processes is currently in use. Although the details of these processes differ significantly, most forming processes share certain characteristics. Each forming process, however simple, can be viewed as a system. For sheet metal forming, one common breakdown of the forming system consists of the following inputs:

- Product design
- Tooling
- Material
- Lubricant
- Press
- Operator

Each of these six major inputs can be further broken down into a multiplicity of subinputs.

The inputs of forming systems are highly interactive. Not only are the changes within a single input difficult to trace and understand, but the interaction of the inputs makes the task even more complex. Small changes made in one or more inputs of the system can cause significant changes in the output of the system (the finished part). These synergistic changes may not be predictable or even possible to anticipate.

The product design usually is not considered by press shops to be an input affecting the forming system. However, some characteristics of the product design are the root cause of the variability of both the output of the forming system and the dimensional stability of the

finished product. An example is stretching a character line with a radius-to-thickness ratio less than four. Incorporating this severe character line into the design of the tooling can produce a range of strain distributions from relatively flat to a severe gradient (Fig. 1a). In a pure stretch operation, the area under the curve is a measure of the traditional increase in length of line. Both curves have the same area under the curve with equal increase in length of line and therefore have identical formed shapes.

The solid line represents a relatively stable condition. Any change in the inputs will be evenly distributed among all elements of the stamping and will result in a small increase or decrease in the level of straining. A flat strain distribution is said to desensitize the stamping to variations in system inputs.

The severe gradient (dashed line in Fig. 1a) creates the opposite effect and is very sensitive to changes in system inputs. Because a majority of the deformation is concentrated in a small segment of the gradient, any changes in the system inputs also are concentrated in the same small segment of the gradient and therefore are magnified. The change in the gradient from maximum to minimum values (Fig. 1b) has a major impact on the stamping. The change in flow stress due to work hardening varies the amount of elastic stress, resulting in differences in springback. Even worse, the increase in localized strain creates a localized thinning. This

**Fig. 1** Schematic (a) showing equal increase in lengths of line (average strain) created by a sharp gradient (dashed line) and a relatively flat gradient (solid line). Schematic (b) showing how a sharp strain gradient (dashed curve) concentrating deformation in a narrow band can vary radically with small changes in incoming system inputs.

local thinning acts like a hinge that allows the change in elastic stresses (a system interaction) to maximize the dimensional variation of the stamping.

Ideally, the forming system should be a continuous process. For many processes, the system appears to be continuous. The tools are inserted into the designated press and remain there for the production life cycle of the part, which often spans several years. Changes made during the production life cycle may in fact create major disruptions in the continuous nature of the process. These changes can include engineering modifications, tooling replacement, routine maintenance, process improvements, and other seemingly minor modifications to the process.

Many forming processes are conducted on a batch basis. Tooling is inserted into a press, a specific number of pieces are made, and the tooling is removed from the press. This type of process is often considered to be an interrupted or segmented form of a continuous process. In reality, however, a new forming system is created each time the tooling is inserted into the press. This often is evidenced by the extended period of trial-and-error adjustments necessary to the tooling before the production of satisfactory parts can begin (Ref 1).

The Statistical Approach

Statistical process control programs are becoming commonplace in industry. An entire science has been developed to deal with the problem of defining, analyzing, correcting, and controlling production processes. References 2 to 5 are several early references. Today (2005), many textbooks or reference books on quality control, process analysis, or process troubleshooting will detail numerous methods of statistical analysis. By providing data on the capabilities and output of a process, these statistical methods provide a rational and analytical, rather than an emotional and guessing, basis for problem solving and decision-making. Other benefits of SPC have been listed in the introduction to this article.

As a system, the forming process is amenable to system analysis and the techniques of system control. Various statistical techniques, many of which have their origins in quality-control practices, can be applied to the forming process. In this article, these statistical techniques are divided into two broad categories: historical tracking and experimental design.

Historical Tracking

Historical tracking is a process of measuring, recording, and analyzing one or more specific characteristics of a process. This record then becomes the basis on which the current state of the process can be assessed and the future state of the process predicted. Numerous stat-

istical techniques are available for historical tracking, ranging from very simple evaluation of a few pieces of data to more extensive mathematical analyses, such as control charts and statistical deformation control.

Two keys are applicable to any analysis technique. The first key is having a data acquisition system or measurement device with a measurement error approximately an order of magnitude less than the process variation being measured. Much has been written about calibration and repeatability of instruments, and again, a whole science has evolved around these procedures. Yet, passing calibration and other tests may be insufficient if the measurement error of the instrument/operator combination approaches that of the production variation of the process being measured. Assume an ultrasonic thickness gage for measuring thickness strain in a sheet metal stamping has a measurement error of  $\pm 0.0001$ . Likewise, the process producing the stamping has a variation of  $\pm 0.0001$ . Are the measured changes due to process variation or measurement error? In this case, no conclusions can be made relative to the source of process variation.

The second key is to analyze data at the most fundamental level. Averaging data loses information. A simple example is to average the steamy temperatures of summer with the icy temperatures of winter and conclude that, on the average, the weather in your city is comfortable.

Simple Analyses

Careful, logical acquisition of data is the heart of any statistical analysis program. The simpler the data system, the better the analysis. The following examples illustrate how averaging data loses information or how important additional information may be overlooked when press shop data are recorded. Sometimes, causes of deformation are detected by accident. More important are statistical records of when problems occur and subsequent analysis of these records. When does the problem occur? Only on rainy days? Only in the summer? Only when edge mults from the master coil of steel are being run? These are only a few additional examples of what good observation and data recording can detect.

**Example 1: Breakage in One of Two Symmetrical Stampings.** A complaint from a manufacturer of symmetrical stampings requested a better-quality metal because a 10% breakage was experienced during the previous run. However, the raw data from the press shop floor indicated that all breakage occurred in the left-hand stampings and none in the right-hand stampings. Because both hands were formed simultaneously in a single die, the raw data changed the focus of the investigation from the metal to the tooling and the press. Either could have caused the left-hand stamping to be more severe than the right hand. One simple test,

rotating the die 180° in the press, showed the problem was in the tooling. The high breakage rate stayed with the left-hand stamping.

**Example 2: Production Run with 4% Breakage.** An accurate count of each stamping that broke was carefully generated and then converted into a 4% breakage for the entire run. The breakage rate was an accurate number, but much information about the root cause of the breakage was lost because the time each broken stamping was made was not recorded. Had the breakage times been recorded and summarized, then different probable root causes could have been assigned, as shown in Table 1. The time of breakage data allowed the corrective action to be focused on one of six probable causes instead of beginning with no focus.

**Example 3: Process Average Hides Process Variation.** A critical part dimension was measured on stampings produced on two different press lines. All parts were reported to be within specification, and the average dimensions of parts from both presses were identical. However, if the data had been plotted on a frequency graph, a very different analysis would have emerged (Fig. 2). The graphs show all parts are within specification limits, and the average or mean values for both presses are identical. However, the dimensional distribution is very different. Press line 5 is producing more consistent parts compared to press line 2 and therefore is the preferred line for that part. This preference for press line 5, however, cannot be extrapolated to any other parts. New data are

Table 1 Data analysis based on time of stamping breakage

Time of breakage	Probable root cause
All at die transition	Insufficient die transition settings
All on one third shift	Substitute operator
All from one coil of steel	Incorrect coil of steel
All during meal breaks and shift changes	Die temperature cooled
All after die maintenance tweaked the die	Draw bead was rewelded to print
Ones and twos throughout run	Process at edge of forming limit

Fig. 2 Schematic showing wide distribution of dimensions for parts made on line 2, but tighter distribution for line 5

required for each part because the interactions of all the system inputs will be different.

### Control Charting

The heart of many SPC systems is the control chart. The control chart is a method of monitoring process output through the measurement of a selected characteristic and the analysis of its performance over time. Because the output from one process usually is the input to the next process, the physical location of the measurement can be at either end of the transfer link. For example, the blanks from a blanking press become the input to the next operation, which usually is the forming press.

A control chart can be a very powerful statistical tool. Information from the control chart can be used to inform the operator when to adjust the process and, perhaps more important, when not to adjust the process. This allows the operator to control the process based on statistically valid

numbers instead of trial and error or, even worse, emotion.

For example, the operator is given a machine capable of producing the required parts and is then given the means to measure the characteristics of output (the finished parts) in real time. Thus, the operator knows the quality of the part coming off the machine on a real-time basis. In addition, the operator has control limits for the process. These control limits tell the operator when to adjust the process and when not to adjust the process, which permits the operator to prevent rather than detect defects. Such a system for the control of steel sheet thickness is described in the following example.

**Example 4: Constructing a Control Chart for Steel Thickness Measurements.** Uniformity of blank thickness is often stated to be important for high productivity in sheet metal forming operations, although published information on this subject is limited (Ref 6, 7). Once the tooling is set for a specific sheet thickness, adjustments to the tooling cannot be readily

made. A control chart can be constructed to statistically monitor variations of the incoming steel.

For each coil of steel received, five blanks are sampled at specific locations along the length of the coil, such as the head, quarter, center, quarter, and tail locations. Examples of such measurements are given in Fig. 3.

The values of  $\bar{X}$  (the average thickness) and  $R$  (the range of thicknesses) are plotted on the respective graphs. After sufficient measurements are made, the  $\bar{X}$ -value and the upper and lower control limits (UCL and LCL) can be calculated and plotted on the same diagram.

The control chart shown in Fig. 3 indicates that the thickness of the steel being processed is stable. A process is said to be in a state of statistical control if it is operating without special causes of variation (Ref 5). It will exhibit random variation within calculated control limits and will have predictability. Measurements taken in the future are expected to be within the same control limits. However, no prediction can

Coil number	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20

**Fig. 3** Raw data (in millimeters; 1 in. = 25.4 mm) obtained from steel thickness measurements and the resulting  $\bar{X}$ - $R$  control charts. Upper and lower control limits (UCL, LCL) can be calculated and the mean determined when sufficient data have been collected.

be made about where any individual measurement will lie within these control limits.

Unfortunately, the control limits shown in Fig. 3 are rather wide and would require frequent tooling adjustments. This means that a normal distribution of thicknesses within the control chart would be expected. However, this expected range is too large for the tooling and would necessitate tooling adjustments to accommodate changes in thickness between the extremes of the range. Therefore, it is necessary to work with the steel supplier to reduce the range of the control limits to an engineering specification window acceptable to the tooling.

Control limits are important in SPC because they define the amount of variation in a process due solely to chance causes. A process operating within these limits (Fig. 4a) is considered to be stable. A process operating outside these limits (Fig. 4b) is unstable.

The control chart represents the best that the operator of a given process can do with the

process as it exists. If this is unacceptable, then the basic process must be changed. Engineering and management, not the operator, are required to implement these process changes because this may require new equipment, new tools, new processing sequences, additional stages, or even a new part design. Alternatively, the control limits of many processes can be improved by simple preventive maintenance, replacement of worn components, and bringing the tools to original performance specifications.

If the process is operating within its control limits (statistical control), then the capability of the system to meet specifications can be assessed. If the system is out of control, then changes to the process must be made to make the process stable before the capabilities can be assessed.

Control charts are most effective when monitored over an extended period of time. Then, changes in the process can be detected, often before rejects begin to occur. Two general types

of changes in the process may be encountered. One is the central sample tendency,  $\bar{X}$ , which is monitored to detect a shift in the location of the distribution (Fig. 5). A location change would imply that the normal distribution remains the same but that the average is displaced. An example in forming may be the angle of a bend. The variation from bend to bend would remain acceptable, but the average angle of all bends would have changed. Some factors that may affect the  $\bar{X}$ -value are gradual deterioration of the equipment, worker fatigue, accumulation of waste products (such as excess lubricant or flaked metallic coatings), and environment.

Another type of process change is a change in the sample range or the variation from one sample to another (Fig. 6). This range change is observed as a change in the width of the normal curve for a given area under the curve. This means increased variability. For the bending example shown in Fig. 5, the average bend angle would remain the same, but large differences would be detected among samples from the same lot or even consecutive samples. Some factors that may affect the  $R$ -chart are changes in operator skill, worker fatigue, change in the mix of components feeding an assembly line, and gradual change in quality of the incoming material.

The two key concepts that emerge from control charts are control and capability. The term *control* defines the stability of the process, which in turn means that the process is predictable. It does not necessarily mean that the process is acceptable with regard to the specification. This is in contrast to the term *capable*, which means that the process has the capability to meet specifications.

**Example 5: Solving a Problem of Fender Blank Size Variation.** Two fender blanks were generated with each stroke of a blanking punch (Fig. 7a). Measurements of the critical dimension y-y on each blank showed large variations in  $R$ -values, but  $\bar{X}$ -values were quite constant (Fig. 7b). Further analysis of individual plots of the right-side blanks and the left-side blanks had different characteristics (Fig. 8). These data showed a reduced variation in  $R$  but a larger variation in the  $\bar{X}$ -values. Interestingly, the  $\bar{X}$ -values of the right- and left-side blanks changed simultaneously but in opposite directions.

Further observation of the blanking process revealed frequent tandem adjustment of both the right- and left-side guides in response to changes in the width of the coil of steel. Even if the coil of steel did not change in width, movement of the right and left guides would cause one blank to increase in width while the other blank would decrease in width. This would cause the range to increase equal to twice the amount of the guide shift.

The first process change made was to weld the left-side guide into correct position. This meant that the left-side blank had the correct width regardless of the width of the coil. As a result, all

**Fig. 4** Distribution curves (histograms; left) and control charts illustrating processes that are (a) in control (within control limits) and (b) out of control (outside of control limits). Variation outside of assigned control limits is always the result of some assignable cause, as shown in (b). UCL, upper control limit; LCL, lower control limit

blank width variations were associated with the right-side blank, and these variations could be related to the variations in the width of the coils of steel. These control charts could be given to the steel supplier as a performance review of the as-supplied coil width variations.

#### Problem Solving Using Control Charts.

Control charts are only signals to operators and management of the operating conditions of the process. Personnel must respond to these signals and identify the sources of the variations. Control charts are useful in many problem-solving situations (Ref 5); they can:

- Assist in distinguishing between special and common causes of variation
- Help determine whether unacceptable variations can be improved by the personnel immediately involved in the process (such as tightening a loose tool holder) or whether they are due to the system and can be corrected only by management
- Identify trends in the process average
- Highlight increased process variability

The opportunities are limitless for using control charts as a key SPC tool. Data collection is the easiest aspect of the process. Finding

the cause of a problem will often require some difficult detective work, and elimination of the problem may be a major task. For example, recording the arrival times for a scheduled shuttle bus is easy. Determining the real cause of deviation from the schedule may be difficult. Periodic high traffic density may be due to maintenance being performed on an adjacent street. To make the shuttle bus immune to delays and to improve trip time consistency would require a major study and perhaps drastic modifications to the traffic control system.

#### Statistical Deformation Control

Four of the six inputs of a forming system (material, lubricant, tooling, and press) can be tracked using the SPC techniques described previously. Typical measurements could include:

- Material thickness, coil/blank dimensions, and properties
- Lubricant composition, viscosity, and application thickness
- Tooling pressures, surface treatment, and dimensional accuracy
- Press speed, stroke, and ram pressures

Many of the aforementioned measurements are charted in an attempt to reduce process variability and to improve product quality. Product design changes are easily identified. On the other extreme, system interactions by the press operators and tooling maintenance personnel are very difficult to track.

The components of forming systems are complex, interactive, and synergistic. Reliable models are becoming available for predicting the output of the forming system based solely on the system inputs. Unfortunately, accurate measurements of all the necessary inputs, such as point-to-point values for both friction and workpiece temperature, are difficult, time-consuming, and even impossible to obtain. Therefore, monitoring of the final output of the system is required. Dimensional checking of the final product can be easily accomplished, but monitoring forming severity requires a different type of measurement. These include sheet metal surface strains, thickness strains, and forming severity ratings.

Numbers representing the parts per million of defects or the percentage of breakage are traditionally recorded to represent the status of the forming system. These numbers are inadequate measures of forming severity. For example, many stamping processes result in high levels of strain but not breakage. Therefore, the absence of splits gives no indication that breakage may be imminent. Some measure of performance must be sought that permits a broader range of conditions. Once breakage begins, the stamping process is out of control. General global straining ceases as the tear develops and opens. In addition, the percent breakage measurement averages the forming severity over a large number of stampings instead of determining the forming severity at a preselected location in each individual stamping. For these cases, percent breakage does not accurately define the various levels of severity.

One means of evaluating forming severity used in many sheet metal press shops is circle grid analysis and forming limit diagrams; these are described in Ref 8 to 11. The actual amount of deformation that the sheet has experienced is determined from the deformed circles (Fig. 9). The forming limit diagram shows the maximum amount of deformation a stamping can undergo before failure. Forming severity can be defined as the maximum allowable deformation minus the actual deformation. This forms the basis for monitoring and controlling stamping performance.

The process of gridding the blank before deformation and measuring the deformed circles presents logistical problems if it is used for routine analyses of a large number of stampings over an extended period of time. These problems include removing blanks from the material lifts for gridding, the time required for gridding, careful reapplication of lubrication to duplicate production levels, reinsertion of blanks into the production cycle without stopping production, proper lighting for grid reading, the time required

Fig. 5 Shifting of a control chart (upper and lower control limits, or UCL and LCL, and mean) due to a change in processing. Values of  $R$ , the range of thicknesses, remain the same.

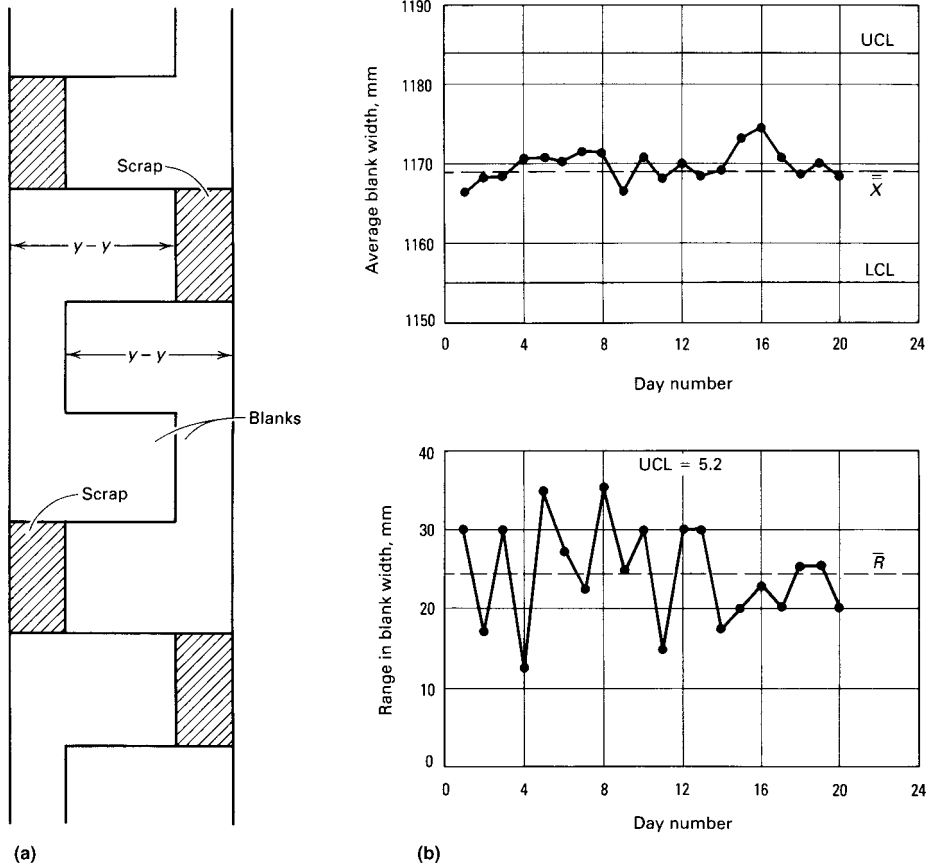

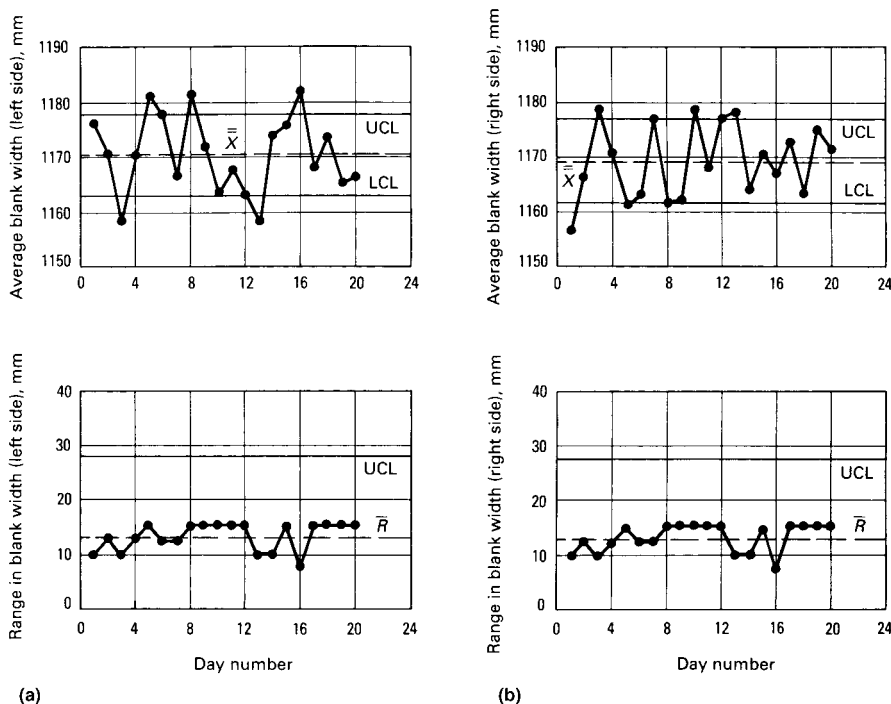

Fig. 6 Increase in the range of values within a subset (increase in  $R$ ). Values of  $\bar{X}$  remain the same.

**Fig. 7** (a) Schematic showing nesting of blanks for an automobile fender. Dimension  $y-y$  was monitored for the statistical process control study reported in example 2. (b)  $\bar{X}$ - $R$  control charts for both right-side and left-side fender blanks are taken as a single population. See also Fig. 8.

**Fig. 8**  $\bar{X}$ - $R$  control charts for (a) left-side fender blanks and (b) right-side fender blanks taken as separate populations

for accurate reading, and disposal of gridded blanks after analysis. Therefore, only one or two stampings are commonly gridded to provide a single analysis (with respect to time) of the severity of the stamping. No information can be deduced about the change of the forming system with time, nor can the single stamping be characterized with respect to the dynamic changes of the system.

Dynamic changes, however, can be analyzed with SPC. A critical variable is measured at specified intervals and plotted as a function of time to generate a control chart. From this control chart, using SPC analysis techniques, the current status of the system can be identified relative to its historical performance. The dynamic variability of the system can be defined, and determinations can be made as to whether the system is in control, out of control, or changing.

Statistical deformation control (SDC) combines the best features of circle grid analysis, forming limit diagrams, and SPC (Ref 12). The deformation severity of the stamping under investigation becomes the critical variable that is tracked by SPC. To simplify the press shop procedures further, the amount of deformation experienced by the stamping is defined by the ratio of final thickness,  $t_f$ , to initial thickness,  $t_0$ . The thickness ratio is determined from ultrasonic measurements of sheet metal thickness in the most critical zone of the stamping. The ultrasonic measurements are rapid, the blanks do not have to be gridded, and the stampings are not damaged by a grid and therefore need not be scrapped after the measurement is made.

Like most analytical tools, SDC does not involve a single, invariant procedure. Several levels of complexity are possible, and each level contributes an increased degree of understanding of the forming system. These levels are:

- **Level 1:** generating a standard control chart
- **Level 2:** assigning a deformation severity value
- **Level 3:** separating material variability from process variability
- **Level 4:** determining sensitivity of the forming system to individual inputs

Again, like most analytical tools, SDC is flexible and should be applied only at the level necessary to solve the problem. Therefore, routine applications of SDC to a system that is in control will be at the level of the basic control chart.

All levels of SDC require a preliminary stamping analysis. Measurement of deformation at the critical location is a key element of SDC. Therefore, an early circle grid analysis of the stamping in question is required to identify the location, mode, and severity of strain in the most critical zone within the stamping. Repetitive ultrasonic measurement of many stampings over an extended period of time requires a template to be made for the ultrasonic probe; the simplest template is a section of an identical stamping with a hole drilled for the head of the probe.

**Fig. 9** Forming limit diagram showing strain states where forming is safe (below curve) and where stampings will begin to fail from localized necking during forming (above curve). The strain values are determined from deformed circle grids placed on the blank before forming.

Template holes are drilled for the most critical location and for an area of the stamping that is undeformed. The latter location determines the initial thickness of the stamping to generate the final-thickness-to-initial-thickness ratio without the inconvenience of premeasuring the blank thickness. The ability to measure critical and initial metal thicknesses on the formed stamping means that random stampings can be selected for evaluation after production.

**SDC Level 1: Control Charting.** Standard control-charting procedures are used. A typical application would require the removal of five stampings in sequence at the end of the press line. Measurements of the thickness in the critical zone and an undeformed zone would be made, and the thickness ratio calculated. These five ratio values would then be converted into the traditional  $\bar{X}$ -R values and plotted on the control chart. Standard control chart analysis procedures are used to calculate upper and lower control limits and other SPC data.

**Fig. 10** Control chart of average thickness ratio  $t_f/t_0$  for a stamping, where  $t_f$  is final thickness, and  $t_0$  is initial thickness. Note the increase in forming severity (reduced thickness ratio) beginning at week 21 and the continuous decrease in thickness ratio beginning at week 25.

**Fig. 11** Severity zones added to average thickness ratio control chart in a level 2 statistical deformation control analysis

The control chart is monitored to determine the viability of the forming system and to initiate corrective actions when such actions are mandated (Ref 5). The importance of these analyses is the predictive capability, which can provide early warning of impending forming process failures. Therefore, SDC can be used to show an increase in the forming severity for a press line for which breakage is not yet a problem, as in the following example.

#### Example 6: Tracking a Sheet Metal Forming System by Monitoring Metal Thinning.

An appliance stamping for a range top was selected for study, using sheet metal thinning as a measure of stamping severity. Measurements were conveniently made with an ultrasonic thickness gage, which permitted measured stampings to be returned to the production line without loss of the stampings. Because breakage was not a problem with this stamping, measurements were made only twice a week. The results of the measurements are shown in Fig. 10.

The stamping was shown to be out of control. However, because the amount of metal thinning did not cause breakage, the stamping was not on the list of problem stampings. After six months of good performance, the amount of metal thinning began to increase. Eventually, excessive production breakage of the stampings began to occur. Because this was a test of the SDC procedure, no attempts were made to determine the cause of the increased thinning or to correct the cause. This would have disrupted the test and would have changed the database. However, the test did show that the stampings that were not breaking could be statistically tracked over extended periods of time in order to detect changes in severity that would lead to production problems if left uncorrected. The absence of breakage in a forming process does not necessarily indicate that the process is in control.

**SDC Level 2: Severity Assignment.** A unique feature of SDC for formability analysis is that each control chart can be subdivided and calibrated according to forming severity for each type of stamping made in the press shop. This severity assignment is independent of whether the process is in or out of control. The severity ranges are assigned based on the thickness forming limit diagram (Ref 12). The following example shows how a process can be in control and producing good stampings and yet have an insufficient safety factor for good long-term reliability.

#### Example 7: Assigning a Severity Rating for Stampings with Only Sporadic Breakage.

Sporadic breakage was occurring in an automotive stamping. The question was asked whether this breakage was the result of random events not typical of the normal system or whether the system was in fact critical and the breakage was a normal by-product of statistical swings in severity. To determine this, metal-thinning readings were made for several weeks (Fig. 11). The control chart showed that the system was in control.

Additional information was gained, however, when deformation severity zones were added to the control chart (Ref 12). The severity zones showed that  $\bar{X}$  was in the marginal zone and that some proportion of the control chart data points fell in the breakage zone. This meant that the sporadic breakage was normal for the system as established and could be expected to continue as long as the process was maintained as currently designed. However, the process was in control and therefore amenable to a process change that would lower the upper control limit from the failure zone into the marginal zone.

**Specifications, Control Limits, and Forming Severity.** An important point of understanding is the differences among engineering specifications, control limits, and forming severity. A specification may require a stamping to have a maximum metal thinning of 42% to meet in-service performance requirements. The control limits indicate whether the process is in statistical control. The state of being in statistical control means that all special causes of variation have been eliminated and that only common (random) causes remain. Special causes are intermittent sources of variation that are unpredictable or unstable. Sometimes called unassignable causes, these variations are signaled by points beyond the control limits. An example of a special cause would be inserting the wrong material into the forming process. On the other hand, common causes of variation are always present and indicate the random variation inherent in the process itself. An example of this would be excess gap in the punch guidance system. Forming severity is the proximity of a given stamping to breakage. This forming limit is independent of future in-service performance requirements or part-by-part variation over time.

**Example 8: Comparing Engineering Specifications and Forming Severities to Control Charts.** Engineering specifications, control limits, and forming severity for a control arm are illustrated in Fig. 12. The allowable maximum metal thinning specified by the part print (engineering specification) is rather high. In fact, the engineering specification is in the failure zone of Fig. 12. This means that the stamping would fail before attaining the maximum thinning allowed by the engineering specification. Therefore, the practical thinning limit of the process is established by forming severity rather than engineering specifications.

The control chart and its attendant control limits reflect the current operating status of the forming process. Figure 12 shows the operating status of the control arm to be in control but with a certain portion of the control chart in the failure zone. This means that some quantity of pieces will break in the forming process. Alterations to the forming process, such as modifying the lubricant or changing the die radii, could narrow the control limits shown in Fig. 12 but would not change the position of the engineering specification or the severity limits. The initial assessment of forming severity and the tracking of

the severity through the production life cycle of the stamping, especially through tooling modifications, are important aspects of SDC.

**SDC Level 3: Material versus Process Variability.** Statistical process control or statistical deformation control can easily identify a forming system that is out of control. Determining the cause of the variability is a more difficult problem. An important first step for most press shops is to separate variability in incoming material from process variability (for example, lubricant, tooling, press, and other in-house variables).

Statistical deformation control provides a method of separating this variability. First, a lift of blanks from the reference material is set aside. This reference material typically would be production material that has average, but consistent, properties. Ideally, this would be verified by evaluating the mechanical properties and surface characteristics of the top and bottom sheets of the lift.

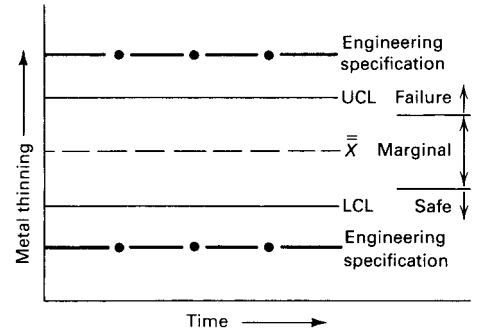

Each time a control chart measurement is made with production material, an equal number of identified reference blanks are also formed, and the severity is measured. Two charts of severity versus time are maintained: one for the production material and one for the reference material (Fig. 13). Comparison of Fig. 13(a) and (b) indicates whether the system variability is due to the production material or the process.

The forming severity of the production steel in Fig. 13(a) is varying, while the forming severity of the reference steel is relatively constant. This indicates that the process parameters are producing a stamping of constant severity and that system variability is due to incoming material variability. The reverse is true in Fig. 13(b) because the variability of the production material is identical to that of the reference material. This indicates that all variation in forming severity is due to process variables.

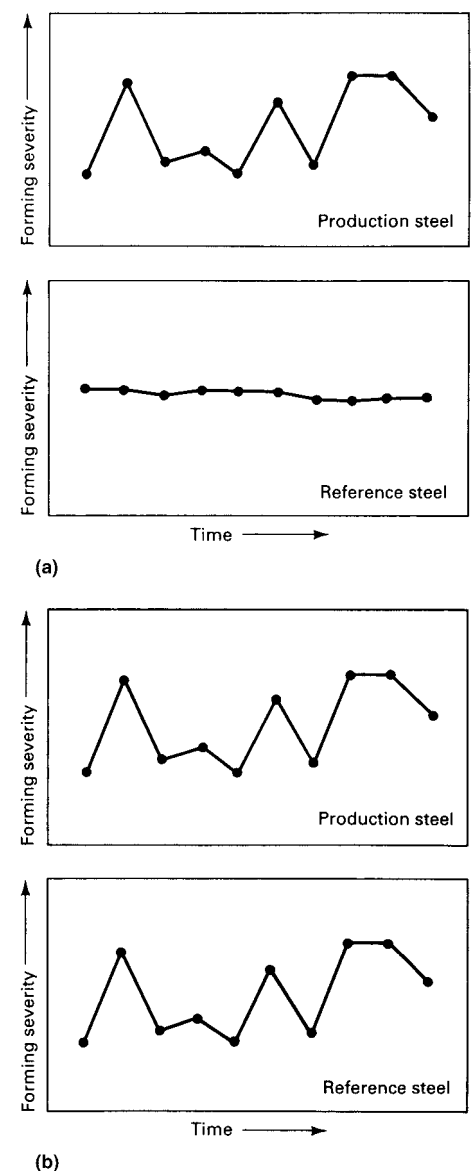

For most forming processes, the forming severities of both the production material and the reference material will vary but will not be identical to each other. This indicates the common situation in which both the material and the process affect the output of the forming system. The variability must then be apportioned between material and process.

Assume that all the variation is caused by variation of process inputs within the stamping plant. The next step would be to further narrow the location of the variation. The aforementioned experiment is not repeated. Instead, a series of stampings are taken after the first forming operation and from the end of the line. If the variation after the first forming operation duplicates the variation at the end of the line, the cause of the variation lies within the first forming operation or earlier. If no variation is measured after the first forming operation, the search for the source of variation is focused on operations performed subsequent to the first forming operation.

**SDC Level 4: Input Sensitivity.** Once the forming system variability has been identified as

**Fig. 12** Schematic control chart showing the differences among engineering specifications, control limits, and severity zones

**Fig. 13** Schematic control charts showing (a) the effects of materials variables and (b) process variables. The identical variations in forming severity for both production and reference steel in (b) indicate that the fluctuation in severity is caused by process variables.

being either material or process related, a more detailed analysis can be conducted to minimize this variability. A key control factor is identified and changed to determine the improvement to the system variability (or conversely, system stability). Selection of the factor should be based on experimental techniques.

There are at least two analysis possibilities. One is to process the new material according to the modified specification, for example, a new metal thickness. This new material parameter is then processed with the reference material and the severity data compared. The key is to run the reference material with the new material in order to isolate material variability from process variability.

A second technique would be to substitute the modified material (alternate parameter) for the reference material. Severity data are then collected for the regular production material and the modified material. The two severity curves can be compared to separate the process variability (Fig. 14) and to permit judgments about the relative performance of the two conditions. If sufficient data points (usually greater than 25) are collected, complete control chart information can be calculated.

The importance of SPC and SDC can be illustrated by describing two alternative methods of process control and analysis, both of which contain major flaws. One common method of process analysis is to produce a large quantity of output (in this case, sheet metal stampings)

with condition A (the first level of the parameter under investigation, such as material properties, type of lubricant, press setting, and so on). The next step is to produce a large quantity of output with condition B (the second level of the parameter). The percentage of part breakage for each is then compared. A major problem exists if breakage is zero for both levels of the parameter under study. Even if the breakage is different for the two conditions, one cannot determine if the difference is due to the change from condition A to condition B, a change in the process itself, or normal statistical variation.

A second method of process analysis is to produce one stamping with condition A and one with condition B. The stampings are compared in some manner, such as degree of tearing or visual quality (Fig. 15). The argument is made that if two sequential stampings are produced, then the process is unchanged. However, statistical information is needed to compare the relative change of the two stampings with the normal expected statistical change between any two consecutive stampings without any intentional system changes.

If the forming system is unstable, then the system must first be stabilized before any changes are made and documented. The following example illustrates how SDC can be used to identify the sources of processing difficulties.

**Example 9: SDC Analysis of an Outer Side Panel of a Truck Body.** The production of a

truck outer side panel was marked with sporadic breakage problems. First, high breakage rates were recorded in area A of Fig. 16 for limited but specific lots of steel brought to the press. Mechanical-property evaluation of these high-breakage lots showed certain formability parameters to be equivalent to those measured in other lots of the same steel type that did not break. Second, certain extended runs of the part experienced more incidents of breakage than other runs.

**Process Analysis.** This problem was selected as an early trial for SDC. The following six steps were used.

First, a circle grid analysis of the stamping was performed using a sheet of the current production material that was satisfactorily making the stamping (Ref 8–12). The most severe strain was located in area A of Fig. 16. Plotting this strain state on the forming limit diagram showed a safety margin of 8 strain percent. This means that the stamping had marginal severity but would not be expected to fracture if the current conditions of the forming system were maintained.

Second, the circle grid analysis showed no strain in area B of Fig. 16. This location was designated as the as-received sheet thickness for purposes of the ultrasonic thickness measurements. This location was ideally suited to thickness measurement because it was at the same relative edge-center-edge location in the coil as the most severe strain location.

**Fig. 14** Control charts showing (a) original spread of process means and (b) reduced spread of process means after a change in the process

**Fig. 15** Measurements from two points in time (values A and B) would suggest that material B has the lower forming severity. However, when full control charts are evaluated, material A has the lower severity.

**Fig. 16** Illustration of truck body side panel showing locations of critical-strain area A and zero-strain area B used for ultrasonic thickness measurements

Third, a template was prepared for the stamping by cutting a section of another stamping to encompass the two locations. A hole was drilled at each location to accommodate the head of the ultrasonic probe.

Fourth, one lot of the production steel that was successfully making the stamping was set alongside the press as a reference lot. Blank edges were marked with yellow paint to identify at the end of the line all stampings made from this reference lot.

Fifth, at the halfway point of each lot of production steel brought to the press, five of the reference blanks were formed. Stampings from these blanks, plus the next five production stampings, were removed from the end of the production line for evaluation. Thickness ratio  $t_f/t_0$  was determined for each stamping. The  $\bar{X}$  and  $R$  values were calculated for both the production steel and the reference steel.

Sixth, concurrent plots of the  $\bar{X}$  and  $R$  values for the production and the reference steel lots were maintained. Sections of the plot are shown in Fig. 17. The mean, the upper control limit, and the lower control limit are not shown because the solution to the problem was achieved before sufficient data points were collected for these statistical calculations.

**Solution.** The left half of Fig. 17 verifies the initial circle grid evaluation that the stamping has some safety margin but that the safety margin is insufficient because the value of the thickness ratio is located in the bottom half of the marginal zone. In this case, it is possible to evaluate the severity of each reading as it is made. The quantity of data points needed to create a control chart is not required in order to determine the forming severity of each stamping.

Both the production steel and the reference steel appear to be maintaining not only a constant

but also an equal forming severity. Neither the production steel nor the forming process provides indications of impending breakage.

When retry lot B (Fig. 17), previously rejected for high breakage rates, was retried, a marked increase in forming severity was noted. The formability of sheet steel is an interaction of substrate properties and the lubricity of the steel/lubricant combination. However, this lot of steel had forming properties equal to or better than the production and reference steels noted in Fig. 17. Therefore, the lubricity of the steel surface was suspected. The steel was coated on the punch side of the sheet with a corrosion-resistant paint. To test the influence of the painted surface, several blanks were turned over so that the bare side of the sheet contacted the punch. These sheets were successfully formed into stampings without breakage. Although unacceptable for production in this reversed condition, these stampings verified that the substrate had sufficient formability to produce the stamping without breakage when the interface friction was correct.

It was recommended that the painted (punch) side of the blanks be sprayed with lubricant if breakage was encountered with a specific lot of steel. If breakage persisted with the additional lubricant, the lot was to be rejected for laboratory analysis of the substrate properties.

The right-half of Fig. 17 illustrates another problem. When the tooling was reset in the press for another run, extensive breakage was encountered with many of the lots of steel brought to the press. An SDC analysis of the stamping showed that the severity of the stamping for the reference steel had increased to zero safety margin, which meant that the tooling was not performing identically to the previous run. This indicated a different setting in the press was

used or modifications were made to the tooling during the period the tool was out of the press. Discussion with the tool and die staff revealed that the draw beads and binder surfaces of the tooling were reworked in an attempt to reduce low spots in the stamping. This reduced the flow of metal from the binder areas and increased the stretch component required over the punch, thus increasing the stamping severity.

The increased severity was verified when samples of the previous problem lot B were inserted in the tooling. Long splits were encountered compared to the previously encountered slight necking condition. The recommended solution was to encourage additional metal flow from the binder area through reduced binder pressure until the reworked draw beads became reduced in effectiveness through normal wear.

During the first run, production steels A, C, and D had a severity comparable to that of the reference steel. During the second run, production steel E had a lower severity than the reference steel. Therefore, using the reference steel as a common base for comparing various production runs, steel E actually had better formability than steels A, C, and D for the specific stamping under investigation.

Continued collection and monitoring of data during the entire production run was recommended. This would require a number of reference lots. However, the SDC procedure allows for this transition by the interleaf forming (alternate blanks) of both reference steels to calibrate the new reference lot relative to the previous reference lot.

A process for data-based management of the forming system was developed by a team of the Auto/Steel Partnership (Ref 13). In their analysis procedure, the line severity analysis is very similar to the SDC just described.

## Experimental Design

Forming operations span an extensive production life cycle, including design, prototyping, engineering changes, tryout, and production. During this entire cycle, a pervasive question is whether the process can be modified. Process optimization is the usual motivation for this modification. This optimization may mean lower cost, faster production rates, fewer rejects, better quality, and so on.

Some process simulation techniques may be available for determining the steps needed to optimize the process and the effectiveness of the various options. However, most of these simulation techniques are mathematically based and only approximate the system under evaluation (Ref 14–16). Therefore, most optimization studies are conducted on the system itself by selectively changing the system variables and measuring the effects of the changes.

These system studies are most effectively conducted with experimental design. Experimental designs are used to increase the efficiency

Fig. 17 Data for two days of measurements made on the truck body side panel shown in Fig. 16. See text for details.

of information acquisition. Several forms of experimental design are available, and each has advantages and disadvantages. The types of experiments discussed in this article are single-variable studies, multivariable studies, and Taguchi experiments.

### Single-Variable Studies

The most common experiment conducted with forming operations is the single-variable study. Although many variables are identified as affecting the process, only one of these variables is changed at a time.

Single-variable studies are widely used because they are easy to conduct and require a minimum number of experiments. First, one variable is changed, and then another, and so on until all of the variables are tried at the second level. One such experimental design table is shown in Fig. 18. Here the (+) indicates the high level of the variable, and (−) indicates the low level of the variable. The following example outlines the procedure used in a typical single-variable experiment.

**Example 10: Finding Improved Process Settings for the Production of an Automobile Inner Door.** High breakage rates were observed during the die tryout of an automotive inner door. A quality group met and identified seven key factors (controlling variables) that affect this particular forming process.

Two steels and a lubricant were obtained. First, the stamping was made with steel 1 (variable +A); all other variables were kept at their existing conditions. The severity of the process was determined using the thickness ratio analysis discussed previously. The stamping was then made using steel 2 (variable −A).

Next followed the additional six changes (variables B through G) indicated in Fig. 18. The thickness ratio was determined for each change. After all eight experiments were completed, the level of each variable showing the greatest thickness ratio (least amount of metal thinning)

was selected as the new standard operating procedure.

**Problems with Single-Variable Studies.** In this study, one variable was changed while all other variables were kept constant. The problem is that the conclusions obtained from this experiment are valid only if all other variables are kept identical to the experimental value. This type of experiment ignores synergistic effects among process variables. In the experiment described in example 10, the effects of different materials (steels 1 and 2) can be measured only if variable C (lubricant) is maintained at its high level (with lubricant). If variable C is at its low level (no lubricant), misleading results may be obtained. In this case, one cannot deduce what variable A does for all levels of the other variables. Therefore, some type of factorial experiment (orthogonal array) is required.

### Multivariable Studies

Multivariable studies are usually conducted using some form of an orthogonal array. The experimental layouts using these orthogonal arrays yield experimental results such that the effects of varying a given parameter can be separated from other effects. Figure 19 shows a complete orthogonal array, sometimes called a full factorial experiment, for seven variables. These orthogonal arrays have also been termed square games (Ref 17).

The term *orthogonal* means balanced, separable, or not mixed, and this indicates that each variable is evaluated equally for all other conditions. Therefore, for each of the two levels of any variable in the array in Fig. 19, there are 64 combinations of the other variables. For example, for level A<sub>1</sub> in Fig. 19, there are 64 possible combinations of variables B, C, D, E, F, and G. This also holds for level A<sub>2</sub>. Therefore, any effect of level A<sub>1</sub> versus level A<sub>2</sub> is determined in the presence of both the high and low levels of all the other variables.

When the quantity of parameters is increased in these factorial experiments, the number of experiments required increases so rapidly that it may not be feasible to implement the experimental design. The full factorial experiment detailed previously involves 128 experiments. Increasing the number of variables by one doubles the number of experiments required to 256.

The full factorial experiment provides the effect of all the single-variable effects plus all the interactions. If some of the interactions can be ignored or deemed unimportant, then the experiment can be redesigned as a partial factorial. A partial factorial has a reduced number of required experiments. The procedure used in one full factorial analysis is outlined in the following example.

**Example 11: A Full Factorial Experiment for Finding Improved Process Settings for Stamping an Automobile Inner Door.** The same quality group that conducted the experiment described in example 10 realized that the synergistic effects were not being evaluated with a single-variable experiment. The group decided to design a full factorial experiment in which all interactions would be active in the study and all interactions could be calculated from the data obtained.

The full orthogonal array shown in Fig. 19 was used. The same variable assignments used in example 10 (Fig. 18) were repeated in this study. Again, ultrasonic measurements of sheet thickness were used to determine the thinnest area (maximum metal thinning) for calculation

Level of variables	Experimental number								Process variables
	1	2	3	4	5	6	7	8	
A versus B	+A	−A	+A	+A	+A	+A	+A	+A	Steel
Large versus small	+B	+B	−B	+B	+B	+B	+B	+B	Blank size
Yes versus no	+C	+C	+C	−C	+C	+C	+C	+C	Lubricant
Hot versus cold	+D	+D	+D	+D	−D	+D	+D	+D	Die temperature
Normal versus offset	+E	+E	+E	+E	+E	−E	+E	+E	Blank position
High versus low	+F	+F	+F	+F	+F	+F	−F	+F	Blankholder pressure
High versus low	+G	+G	+G	+G	+G	+G	+G	−G	Ram speed

Fig. 19 Layout of a full factorial (multivariable) experimental design for a group of seven variables

of stamping severity. Analysis of the results showed that some of the interactions were very important and had to be considered in selecting the best operating levels of each parameter.

### Taguchi Experiments

Conventional experimental design techniques were primarily developed for use in scientific research in order to determine cause-effect relationships (Ref 17). In science, there is generally only one law to explain a natural phenomenon. Therefore, the primary experimental efforts are aimed at finding the law that explains the relationships being studied.

In technological fields, however, there are numerous ways to obtain a given product design objective. In forming a sheet metal stamping, there are various steel characteristics, die designs, die steels and surface treatments, lubricants, forming sequences, and other variables to be considered. Different combinations

can be used to produce the same end design of stamping. A desirable goal is to find the combination that provides the most stable and reliable performance at the lowest manufacturing cost. The goal of the Taguchi experiments is to develop the most robust process possible (that is, the process that is least sensitive to the causes of variation).

In many cases, knowing the cause of a problem is insufficient for solving the problem. Removal of the cause of the problem may be too costly or even impossible. The Taguchi strategy then becomes one of finding countermeasures that do not eliminate the cause but reduce the influence of the cause on the end product. Efforts are aimed at making the final product insensitive to all process variables. Taguchi techniques are oriented more toward cost-effectiveness and marketing than are conventional experimental design techniques (Ref 17). This difference affects the nature of the parameters to be cited, the way in which the experiments are laid out, and the way in which the data are analyzed. In a sense, the Taguchi method of conducting experiments is formalized to such an extent that only minimal exchange of information is required among experimenters trained in this technique to achieve complete understanding of the experimental parameters, the experiments, the analysis of the data, and the results/conclusions.

Differences between the Taguchi approach to experimental design and the conventional approach are both philosophical and methodological (Ref 17). Philosophically, the Taguchi approach is technological rather than theoretical, inductive rather than deductive, an engineering tool rather than scientific analysis. Taguchi emphasizes productivity enhancement and cost-effectiveness with a rapid, formalized procedure that is not necessarily statistically rigorous. With regard to its methodology, the Taguchi approach emphasizes the application of orthogonal arrays, signal-to-noise ratios (in Taguchi analysis, the variables that affect a process are classified as signal, control, or noise factors), and newly developed analytical techniques (Ref 17).

One primary advantage of the special orthogonal arrays used by Taguchi is the capacity and flexibility of assigning numerous variables with a small number of experiments. An even more important advantage of the array is the reproducibility of the conclusions across many different process conditions. One criticism is that the Taguchi array is nothing more than a fractional factorial, which has long existed in conventional experimental design techniques. However, the Taguchi technique is one of philosophy and content, as explained previously. The application is more versatile and sophisticated.

Further explanation of the Taguchi method or the experimentation/analysis procedures is beyond the scope of this article. Additional information is available in Ref 17 or from the American Supplier Institute (Dearborn, MI). The

following example outlines the approach used in one Taguchi analysis.

#### Example 12: A Taguchi Design of Experiments for Finding Improved Process Settings for Stamping an Automobile Inner Door.

The same seven variables used in examples 10 and 11 are used in this experiment. Selection of the proper experimental variables is extremely important in Taguchi experiments. The variables should be primary variables with little interaction. In studying stamping severity, for example, blankholder pressure (variable F) is not set by the tons of force shown on a load indicator, because the measured tons are highly interactive with all of the other variables of the system, such as blank thickness, metal strength, die temperature, and shims used. Instead, the blankholder pressure variable is controlled by the position of the nut (or turns of the screw) on the outer ram relative to the zero load reference position. The extra time spent identifying and selecting the important process variables is the key to the success of the Taguchi experiment.

Figure 20(a) shows the layout of the Taguchi experiment for the seven variables detailed in example 10 (Fig. 18). The array is a standard array for up to seven controlling variables or factors. The eight experiments required for a full factorial analysis are shown in Fig. 20(b). There are eight rows representing eight experiments, numbered 1 through 8. The elements of the seven columns consist of 1s and 2s. There are four 1s and four 2s in every column. In any pair of columns, there are four possible 1, 2 combinations, namely 11, 12, 21, and 22. Because each of these four combinations occurs at an equal number of times in a given pair of columns, the two columns are balanced or orthogonal. Figure 20 shows that all column combinations have an equal number of 11, 12, 21, and 22 combinations; therefore, all interactions are within the experimental design. After the eight experiments are completed, the data are analyzed according to a prescribed procedure in order to determine the level of each variable that contributes to the most robust (most insensitive process) combination of processing variables.

# Process and Feedback Control for Manufacturing

Mahmoud Y. Demeri, FormSys, Inc.  
Jian Cao, Northwestern University  
Ravi Venugopal, Sysendes, Inc.

TREMENDOUS ADVANCES in automation technology have been made since the 1990s, and the use of this technology in the area of manufacturing has yielded significant benefits. The integration of automatic process control systems in a manufacturing system ensures part quality and consistency by compensating for variations in material properties and process conditions, in addition to other benefits such as round-the-clock operation. While process control has been used extensively for chemical engineering, semiconductor manufacturing, and even processes such as welding, the application of this technology to other manufacturing processes such as sheet metal forming is relatively new. The objective of this article is to provide a basic overview of control system design and elucidate its application to various manufacturing processes.

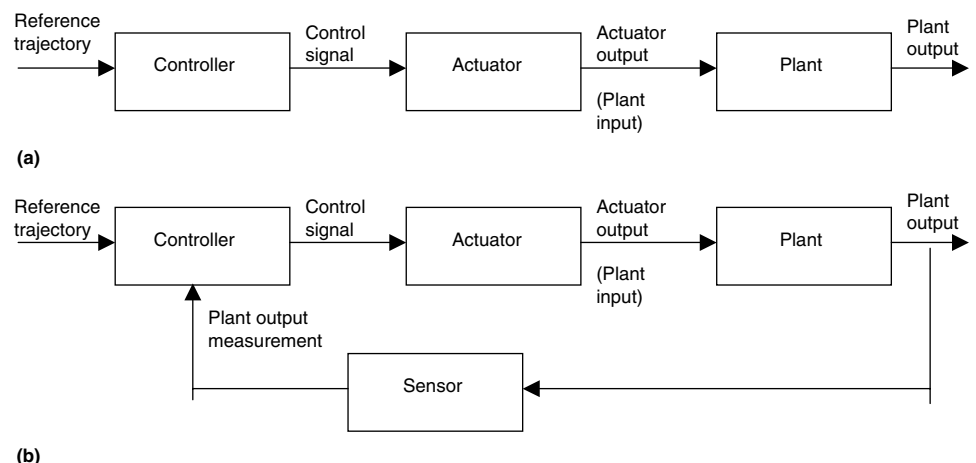

## Basic Concepts of Control Systems

A signal is defined as a representation (typically mechanical or electrical) of a physical condition, and a system is a physical entity with input and output signals. Control systems are used to drive the output signals of the system that is controlled to a desired profile, and this is done by sending mechanical or electrical signals from the controller to a device that directly affects the controlled system. The controlled system is known as the plant, while the device that directly affects it is known as the actuator. For example, the hydraulic ram of a stamping press is an actuator, with hydraulic pressure as its input and punch force as its output, while the metal that is formed is the plant, with punch force as an input and a material deformation measure such as thickness as an output. Systems may have several inputs and outputs; for instance, the blankholder force can be considered as an additional input to the plant in the previous example. The interaction between signals and systems can be represented graphically as block diagrams.

There are two main classifications of control systems, namely, open-loop control systems and feedback (or closed-loop) control systems. In open-loop control, the controller sends the actuator a predefined control signal that is not based on the output of the plant. The control signal is computed based on the desired output of the plant and models of the plant and actuator. In other words, the output has no influence on the control action taken because the output is neither measured nor fed back for comparison with the input. The obvious advantage of the open-loop control system is its easiness in implementation, faster response time, and relatively low capital investment. It is suitable for situations where variability is well under control or process design is robust, meaning that the output is not sensitive to input variations. Open-loop control requires extra demand from process design engineers. Figure 1 shows the input-output relationship of an open-loop (Fig. 1a) versus the closed-loop (Fig. 1b) control system.

When process variation is of major concern, a feedback (closed-loop) control system is highly

recommended, because the control signal will be recalculated based on the current status. Feedback control is based on feedback signals from sensors that continuously monitor the output of the plant. The entire system, comprised of the controller, actuators, plant, and sensors, is known as the closed-loop system. The control signal that the controller sends to the actuator is calculated using the feedback signals from the sensors. Hence, variations in the plant or actuator will be reflected in the sensor output, and the controller will be able to compensate for these changes. In addition, the feedback sensors will also pick up the effect of external disturbances acting on the plant or actuator, and the controller can compensate for these disturbances. Open-loop controllers do not have this feedback information and thus cannot compensate for disturbances that are not modeled. Thus, it can be seen that feedback control systems are more robust than open-loop control systems and can compensate for system variations and external disturbances. However, the design of a high-performance feedback controller is not trivial, because an

**Fig. 1** Block diagrams of (a) an open-loop control system and (b) a closed-loop or feedback control system

incorrectly designed controller can cause closed-loop instability. Note that here *instability* refers to system unstable.

More sophisticated feedback control systems with the added ability to self-adjust their response by changing the gains and/or time constants in their control laws are known as adaptive control systems. Such systems usually require precise knowledge of the relationships between input parameters and the desired outputs.

## Designing a Feedback Controller

The design of a feedback controller involves the following steps:

- Mathematically characterizing the input-output relationships of the plant, actuators, and sensors
- Choosing a controller structure that is appropriate for the desired control objective
- Calculating the parameters of the controller based on the control objectives and the mathematical characterizations of the components of the closed-loop system
- Ensuring closed-loop stability and robustness
- Choosing a method of controller implementation. Controllers are usually implemented electronically, either as analog circuits or digitally on microprocessors, although in rare instances, mechanical means are used.

The design methodology listed previously is a formal approach to controller design. However, it is often standard practice to use a common controller known as a proportional-integral-derivative (PID) controller and to adjust its parameters based on experimental observations. The benefits and limitations of using PID controllers are discussed later in this section.

The input-output relationships of the first step are usually represented as ordinary differential equations (ODEs) that evolve in time, although for metal forming applications, partial differential equations (PDEs) that account for both spatial and temporal variations are usually more appropriate. Most controller design techniques are based on ODE representations of systems, and thus, when the systems are characterized by PDEs, the PDEs are reduced to ODEs by using techniques such as separation of variables and by considering inputs and outputs at certain specified spatial locations of the system. The differential equations that characterize the system are obtained from the physical nature of the system; however, it is very often impossible to find the values of all the parameters in these differential equations. Thus, physical modeling can provide important information about the qualitative behavior of the system and help define the structure of the controller but is often insufficient for accurately calculating the controller parameters. In practice, system parameters are obtained using system identification, a technique by which

parameters are extracted from experimental input-output data. System identification methods can range from simple curve-fitting techniques to sophisticated methods that estimate disturbance and noise properties in addition to the system parameters. However, metal forming processes often involve complex models, and the issue of modeling metal forming processes for feedback control is still an active area of research (Ref 1, 2). Once the mathematical models have been constructed and parameterized, they are validated using computer simulations by comparing simulated outputs to experimental outputs for the same set of inputs. If the mathematical model can be reduced to a linear ODE, Laplace transform methods can be used to obtain a transfer function of the system, defined as the Laplace transform of an output signal divided by the Laplace transform of an input signal. Transfer functions are algebraic representations of linear ODEs, and there are several powerful techniques for studying system behavior based on transfer function analyses (Ref 3).

**Controller Structure.** The selection of a controller structure is now addressed. In the previous section, it was noted that the purpose of using an automatic control system is to drive the outputs of the plant to a desired profile or trajectory in the presence of immeasurable disturbances. This activity is referred to as command following (or tracking) with disturbance rejection. The desired output trajectory is known as the reference trajectory. As in the case of plant and actuator models, most controllers are represented as ODEs. The structure and parameters of the controller ODEs are design variables. In many cases, a linear ODE structure is chosen, and the input to the controller is the error signal, defined as the difference between the reference trajectory and the measured output signal from the plant.

**Proportional Control.** The simplest form of a feedback controller is a proportional or P-controller that generates a control signal proportional to the error signal. For example, consider the problem of driving a roller in a steel rolling mill at a prescribed reference rotational speed. The motor drive is the actuator, and the roller is the plant. The rotational speed is measured by an angular velocity sensor and fed back to the controller. The control signal is the current to the motor. If the speed of the roller is less than the reference speed, the error signal is positive and the control signal (current) is a factor (the P-gain) multiplied by the error. Thus, a positive current will be applied to the motor, which will speed the roller up and bring the rotational speed closer to the desired reference value. If the speed of the roller is higher than the desired reference speed, the error signal will be negative and a negative current will be applied to the motor, which will slow down the roller and bring the speed closer to the desired value. The design parameter here is the P-gain, which is usually denoted by  $K_p$ . If the P-gain is too low, the roller will take a long time to achieve the desired speed, and if it is too high, overshoots may occur,

leading to oscillations or instability in roller speed.

**Derivative Control.** The next extension in control structure is derivative control, or D-control, in which the control signal is proportional to the rate of change of the error signal. Derivative control adds damping to the system by ensuring that the control signal does not cause the output to change too rapidly. The factor that multiplies the derivative of the error signal to yield the control signal is known as the D-gain and is denoted by  $K_d$ . Derivative control is usually used along with proportional control in a PD control structure. While derivative control helps damp out oscillatory behavior, it is sometimes difficult to implement due to the fact that numerical differentiation of the error signal for obtaining the derivative of the error leads to amplification of noise in the error signal. Thus, a high D-gain can result in a closed-loop system that is very sensitive to noise.

**Integral Control.** The final element in a basic control structure is integral control, or I-control, in which the control signal is proportional to the error signal integrated over time. Integral control is usually implemented to overcome steady-state errors by incrementally adding to (or subtracting from) the control signal until the error signal is driven to zero. The factor that multiplies the integral of the error signal is known as the I-gain and is denoted by  $K_i$ .

**Combination Control.** For many applications, a combination of proportional, integral, and derivative (PID) control is used, and the P, I, and D gains are adjusted (tuned) either by trial and error or according to specified tuning rules. Note that tuning a PID controller does not necessarily require a mathematical model of the system, and thus, these controllers are used extensively in practice. However, the structure is constrained and is not always applicable to all systems, especially systems with multiple modes and multiple coupled inputs and outputs. The PID controllers also may not work very well for nonlinear systems.

**Other controller structures** are used to control more complex systems, and optimal control techniques are used to derive controller parameters based on minimizing a performance cost function involving the error signal. There are several factors that contribute to the complexity of a system, for example, a large number of inputs and outputs that are coupled, dynamics that are characterized by high-order differential equations, nonlinearities, delays, time-varying characteristics, and model uncertainty. Over the past 50 years, several advances have been made in theoretical and applied control engineering that address these issues. For example, linear-quadratic-Gaussian control is a method for designing optimal controllers for multiple-input, multiple-output linear systems of any order subjected to random immeasurable disturbances. Predictive control addresses delays in systems, while robust control techniques allow a trade-off between controller performance and system uncertainty. Adaptive control techniques modify

the controller parameters during operation to adjust to system changes and effects that are not explicitly modeled. More information on these approaches is available in Ref 3 to 5. Models of the plant, actuators, and sensors are usually required to design controllers for more complex systems. For example, the autoregressive moving-average model (ARMA) has been used to identify system relationship between multi-inputs and multioutputs. The advantage of this model is its generic nature, and it has been used in various forms of time series analysis and system identification problems (Ref 6, 7). The basic format of the ARMA model can be found in Ref 8 and 9. It is also useful to note that having these mathematical models also makes tuning a PID controller much easier.

**Neural Network Control.** Another approach in control is to use neural network control. The concept of neural network control and potential applications are discussed in Ref 10. Briefly, a neural network mimics the structure of the brain. Through a set of carefully conducted experiments, the network is trained to identify small or large variations in the process and then act accordingly to achieve a preset goal, for example, springback control. Examples of metal forming processes that have benefited from neural network springback control include a rebar (Ref 11) and an air bending process (Ref 12). In Ref 13, a neural network has been used to determine the material properties early in the forming process of a cylindrical part. Closed-loop control of the binder force was then employed based on the theoretical wrinkle limit in the initial forming depth stage of the process and the theoretical fracture limit in the latter forming depth stage. These theoretical limits were based on an analytical calculation using the material properties computed by the neural network and a friction coefficient, which was determined throughout the forming process. A control system using artificial neural networks and a stepped binder force trajectory to minimize and control springback in a channel forming process is discussed in Ref 10, 14, and 15.

**Stability and Robustness.** Once the controller structure has been chosen and its parameters specified, closed-loop stability and robustness are analyzed using analytical and simulation methods. Computer-aided control system design tools are very useful for this purpose. MATLAB from The Mathworks is an example of such a tool. These tools allow the user to predict closed-loop performance based on plant, actuator, sensor, and controller parameters. Simulink, a graphical simulation tool developed by The Mathworks, allows the user to create a numerical simulation of a closed-loop system by graphically defining it in block-diagram form.

**Controller Implementation.** The final stage of controller development is controller implementation. This stage involves creating the physical controller with the error signal(s) as its input and the control signal(s) as its output. The controller operates in real-time and ensures that the control objective is met. The controller may

be an analog circuit characterized by the controller ODE or it may be a digital controller in which a microprocessor runs code that numerically integrates the controller ODE to calculate the control signal. In the case of digital controllers, analog sensor signals are converted to digital form using analog-to-digital converters (A/D), while the digital control output of the microprocessor is converted into an analog signal using digital-to-analog (D/A) converters.

Analog controllers have the advantage of being inexpensive and relatively simple to build. However, modifying an analog controller involves effectively rebuilding it. In contrast, digital controllers are relatively expensive and have to be carefully designed to account for issues related to converting analog signals to digital signals such as quantization and aliasing. However, they are very flexible, and changing controller parameters or structure usually involves modifying the software that runs on the microprocessor of the controller.

A new technology that has significantly reduced digital control development time is rapid control prototyping (RCP). The RCP systems consist of hardware that includes microprocessor(s), A/D, D/A, and other input/output devices; and software that allows the controller designer to define a controller in block-diagram form and have it implemented on the hardware by automatic code generation. The physical device that is controlled is interfaced to the RCP hardware by connecting the sensors to its inputs and the actuator to its outputs. The RCP software also allows real-time monitoring of sensor and actuator signals in addition to all controller variables. Controller parameters can be optimized during operation using an RCP environment, and several controller structures can literally be implemented in minutes. In contrast to traditional industrial automation systems, which allow only basic PID and switching logic controllers, RCP systems allow implementation of any control strategy. dSPACE, Inc. is a leading vendor of RCP systems that are completely integrated with The Mathworks' control system design and simulation tools, MATLAB and Simulink.

At this point, it is also important to say a few words about the generation of the reference trajectory that the control system forces the plant output to follow. This task is an important component in successfully implementing a feedback control system. For example, optimizing the punch force for a stamping process improves the consistency and quality of the formed part, as described in Ref 16. However, determining this trajectory, because a reference input to a feedback control system requires theoretical and experimental analysis of the dynamics of the process, and the actuators, sensors, and control strategy have to be chosen to ensure that this reference trajectory is tracked with sufficient accuracy. The issue of generation of system reference inputs for process control of metal forming processes is an area of active research and is discussed in Ref 16.

## Application Example: Process Control for Sheet Metal Forming

Sheet metal stamping is a primary manufacturing process for high-volume production of automotive panels and components. The quality of stamped parts is important in avoiding assembly problems and in achieving product performance. Major problems with the quality of automobiles, such as wind noise, water leaks, squeaks, and fit and finish, are directly related to the quality and dimensional accuracy of stamped components. The development of production dies and the fine-tuning of the stamping process to produce high-quality parts with low scrap rate is a very expensive and time-consuming process. After production begins, disturbances to the process (material property variations, frictional interface changes, tool wear) may cause many parts to be scrapped due to tearing, wrinkling, or poor dimensional accuracy. This example illustrates a sample problem, its experimental trials and needs for a closed-loop control system, the design of the control system, and system validation.

**Problem Definition.** A stamping system is shown schematically in Fig. 2.  $F_b$  is the applied

Fig. 2 Schematic of a sheet metal forming system.  $F_b$ , applied binder (blankholder) force;  $F_p$ , punch force

binder (blankholder) force, and  $F_p$  is the resulting punch force required to form the part. The binder, with or without drawbeads, is a critical part of the stamping system. While flat binders rely entirely on friction to generate binder restraining forces at the edge of the sheet metal blank, drawbeads rely on bending and unbending of the sheet metal and, to a lesser extent, on friction to regulate the amount of the blank material that flows into the die. Flat binders are more sensitive to variations in friction conditions, die misalignment, and blank thickness variations. If the restraining force is too low, too much material flows into the die, causing wrinkling in the part. If, however, the restraining force is too high, not enough material flows into the die, causing splitting in the part. The binder restraining force has also been found to have a strong effect on the final part dimension through its effect on springback. Different binder force trajectories (step increase, step decrease, and level change) were found to produce different strain histories in the blank material, leading to different formability and springback in the final part. Formability and dimensional accuracy can, therefore, be improved by the proper control of the blankholder force.

In the following example, feedback control has been applied to the process of cup drawing. The control objective here is to apply a consistent punch force, that is, to track a desired reference punch force trajectory while rejecting disturbances in the system. Disturbances in the forming system may include variations in the manufacturing parameters such as frictional behavior, blank thickness, material properties, blank placement errors, and die wear. The binder force-generating unit is used as the actuator. Successful implementation of the feedback control strategy for cup drawing entails forming cups to a specific depth without splitting. Figure 3 shows a picture of a successful and a failed cup.

**Experimental Investigation of Constant Binder Force Cases.** The process of deep

Fig. 3 Picture of a successful and a failed cup

drawing of conical cups involves applying a drawing force with a punch to the center of a circular blank, as shown in Fig. 4. A binder force is applied to the periphery of the blank to control the amount of material flowing into the die cavity. As the punch draws the metal, hoop compression develops in the flange area before the metal bends at the die radius and then straightens as a result of the applied tension in the cup wall. Because the cup wall transmits the punch force to the bending, straightening, compression, and friction areas, a high state of tension develops near the punch radius where the metal thins and most often fractures. For a given material, blank size, and tool geometry, the binder restraining force at the edge of the blank is determined by the level of friction at the sheet metal/tool interface. A change in the level of this force is reflected in a change in the level of the punch force required to form the cup. The punch force is the sum of the forces required to bend, straighten, and compress the metal to conform to the cup shape as well as the force needed to overcome friction between the blank and the tool. In cup drawing, the forces needed to shape the metal remain constant, but the force needed to overcome friction may vary from part to part. Differences in punch force profiles due to changes in friction conditions indicate that punch

Fig. 4 Forces applied to a blank during cup forming process

force could be a good measure of the performance of the cup drawing process.

The instability that occurs in the conical cup drawing process was demonstrated in a laboratory experiment by forming 15 cups under seemingly identical conditions. The cups were made from circular blanks of DQSK-EG steel. The blanks were 0.8 mm (0.03 in.) thick and had a diameter of 200 mm (8 in.). The mechanical properties of this material are given in Table 1. The circular blanks were lightly lubricated with prelube on both sides before being drawn into conical cups. The binder force was kept constant at 575 kN (65 tonf), and the punch speed was held constant at 10 mm/s (0.4 in./s) throughout the stroke.

Experiments were performed on a double-action hydraulic press equipped with a PID digital controller. The press has a load capacity of 680 kN (76 tonf) for the punch and 700 kN (79 tonf) for the binder. The press was instrumented with sensors to measure punch and binder loads as well as punch displacement during a forming process. Additional components were added to the press to permit the construction of a closed-loop control system to track a reference punch force trajectory as the predetermined process variable. This process variable was used as feedback to modulate the binder force in real-time. Process control gains were adjusted to provide stable and acceptable tracking performance. Tooling shape and dimensions used for the conical cup tests are shown in Fig. 5.

Selection of the level of the binder force for the process instability tests was based on studying the effect of constant binder force profiles on the maximum depth of the drawn cups, as shown in Fig. 6. The maximum depth was determined when a split occurred in the wall of the drawn cup.

An examination of Fig. 6 shows that substantial instability occurs when the clamp force is at the 575 kN (65 tonf) level. The maximum depth of the drawn cups at that level ranged between 15 and 45 mm (0.6 and 1.8 in.). This indicates that the forming process, under these conditions, could not be controlled and that the success or failure of the formed cups could not be reliably predicted.

**Needs for a Closed-Loop Control System.** The next phase of testing to determine the instability of the cup forming process was to

Fig. 5 Tooling shape and dimensions used for the conical cup tests

Fig. 6 Effect of constant binder force on punch force and maximum draw depth

draw 15 cups at the selected constant binder force of 575 kN (65 tonf) to find out the extent of variations in cup heights obtained without active binder force control. Similar tests have also been conducted with active binder force control to demonstrate that process control could stabilize the forming process and could produce more consistent cups. Results of the tests, as shown in Fig. 7, indicate that the forming process was not under control and that the success or failure of the formed cups could not be reliably predicted.

If the drawing process were stable, all cups would have been drawn successfully to a maximum depth of 40 mm (1.6 in.). It is evident that in-process variations caused the drawn cups to fail prematurely by tearing. For a constant binder force, tool geometry, blank size, surface finish, and sheet material, frictional conditions appear to be the most significant factor in determining the level of the binder restraining force. Because the level of the binder restraining force is reflected in the level of the punch force required to form a cup, an examination of the punch force trajectories for the 15 drawn cups should provide important information on the instability problem.

Figure 8 shows the punch force trajectories, using constant binder force of 575 kN (65 tonf), for a subset of the 15 drawn cups. This subset, which includes samples 6 through 10, was selected because it had a wide variation in the maximum draw depth obtained during the cup forming process. It is obvious from the figure that there is an inverse correlation between the magnitude of the jump in the punch force trajectory and the failure height of the drawn cups. An increase in the level of the punch force results from an increase in the level of the binder restraining

Fig. 7 Instability of the conical cup drawing process

force. The binder force increases with increase in the level of friction at the binder/sheet interface.

In order for the blank edge to move toward the punch during the cup drawing process, the force of friction between the blank and the die must be overcome. The normal force created by the binder adds significantly to the force of static friction in accordance with Coulomb's relationship:

$$\begin{aligned} \text{Friction force } (F_f) \\ = (\text{Friction coefficient, or } \mu) \\ \times (\text{Normal force, or } F_b) \end{aligned}$$

The blank starts to move after static friction is overcome. Continuous force must be exerted to overcome sliding (dynamic) friction, and this force would be less than that needed to overcome static friction. For a constant binder force, tool geometry, blank size, surface finish, and sheet material, variations in lubrication conditions change static and dynamic frictional forces

through their effect on the coefficient of friction. It must be emphasized that lubrication conditions may not remain constant during the forming process.

**Control System Design.** Punch force is the sum of forces needed to bend, straighten, and compress the metal to overcome friction. Variations in the punch force observed during cup drawing are most likely due to variations in the lubrication conditions. Spikes in the punch force could be related to increases in the static frictional forces caused by changes in the friction condition in the binder area. Increasing the punch force results in a high state of tension in the cup wall near the punch radius where the metal thins out the most, thus causing instability and leading to fracture.

Because the lubrication condition changes during the cup drawing operation, a closed-loop control system must be used to control the forming process. A real-time process controller

was implemented to ensure that the forming process would always give the desired successful cup regardless of friction conditions. Punch force was used as the control parameter to modulate the binder for conical cup drawing. A block diagram of the control system used for tracking the optimal punch force trajectory is shown in Fig. 9. The implementation of the process control strategy shown in the block diagram entails modeling of the forming process, designing an appropriate process controller, and determining an optimal reference punch force trajectory.

A first-order nonlinear dynamic forming process model was developed in Ref 1 to define the relationship between the binder force and the clamp force. A proportional plus integral controller with feed-forward action (PIF) was successfully implemented in the forming press (Ref 2). The controller was designed to ensure good tracking performance in the feedback control system. An optimal punch force trajectory was

selected from the punch force trajectories shown in Fig. 8. Because sample 8 provided the best results for a successfully drawn cup, its punch force trajectory was selected as the optimal reference punch force trajectory for use during real-time process control.

The effectiveness of the real-time closed-loop controller was demonstrated in the lab by forming a second set of 15 cups using active binder force control instead of the constant binder force used on the first set of 15 cups. Shortly after each experiment begins, the system shifts from a constant binder force mode to a punch-force-tracking mode following the optimal reference punch force trajectory. The process controller was operative during the entire stroke of the process. The implementation scheme of process control in the forming press is shown in Fig. 10.

The data acquisition board (DAQ) acquires data from the press digital controller and feeds

the calculated binder force command ( $F_{bc}$ ) into the digital controller. The process controller constitutes the program and the DAQ blocks. The WSCI block refers to the workstation communications interface.  $F_p$  is the punch force,  $F_b$  is the binder force,  $X_p$  is the punch displacement, and  $F_{bc}$  and  $X_{pc}$  are commands to the hydraulic actuators for the binder and the punch, consecutively. The “Program” block collects data, reads, or generates the reference punch force trajectory  $F_{pd}$  and calculates the binder force,  $F_{bd}$ , based on a PIF control algorithm.

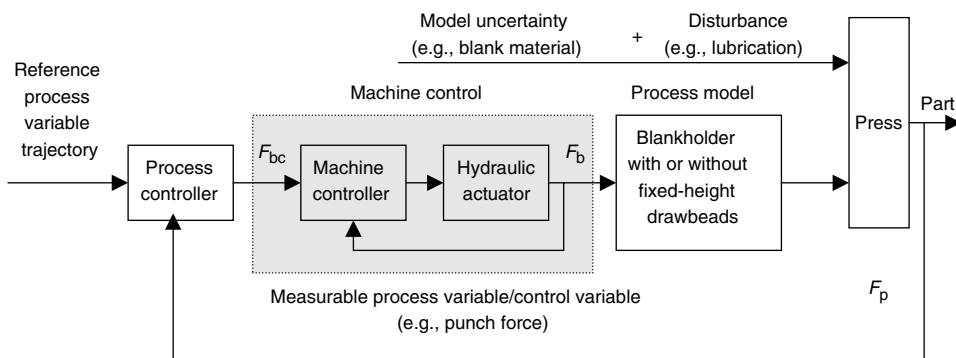

**System Validation.** Results of the tests, obtained using the process controller, are shown in Fig. 11. The results indicate that the forming process was completely under control and that the success of the cups could be guaranteed. The process controller was operating during the entire forming stroke and was capable of maintaining the desired punch force trajectory regardless of the variations in the friction conditions. The punch force peaks, shown in Fig. 8, appear to have been softened by the process controller, as shown in Fig. 11.

The corresponding binder force trajectories needed to maintain the optimal punch force trajectory are shown in Fig. 12. The binder force undergoes modulation to compensate for the process variation in order to follow the reference punch force trajectory.

The conical cup deep-drawing application example showed that the control strategy increased the robustness of the conical cup drawing process by eliminating process sensitivity to variations in the lubrication condition during forming. Results showed that the implementation of active binder force control stabilized the cup forming process and produced successful cups every time.

## Application Examples

**Example 1: Using Neural Network for Springback Control.** Springback variation in final products can be traced back to variations in incoming material, process, and lubrication. The closed-loop control system presented in the previous example of process control for sheet metal forming, using punch force as a target, can be used to control springback due to variations in binder force setup or friction conditions, as demonstrated in Ref 17. In this application example, an approach based on the use of neural networks to control springback in sheet metal forming due to process and material variations, such as thickness, coating, and material properties, is demonstrated. The approach is exemplified in a channel forming process shown in Fig. 13.

As shown in Fig. 14, a stepped binder force, starting with a lower binder force, then changing to a higher binder force at a certain punch displacement, can effectively achieve a low springback amount without overstretching the panel. When variations are present, the challenge

is to find out when to switch to a higher binder force and how higher the binder force should be for a specific case.

**Background—Neural Network.** Neural networks are nonlinear analysis tools that form a highly interconnected, parallel computation structure with several simple processing elements, or neurons. Each neuron is linked to

adjust downstream neurons through variable weights. These weights are calculated by an iterative method during the training process when the network is fed with a large amount of training data, input and output pairs that represent the pattern attempting to be modeled. It has been shown that a two-layer neural network, one made up of an input layer, a hidden layer, and

an output layer, was sufficient to accurately model any continuous function, provided a sufficient number of hidden neurons are used (Ref 18). Therefore, this network architecture was chosen for the current example application. In a fully connected network, each neuron receives inputs from all of the elements in the preceding layer. No connections exist between neurons in the same layer. Figure 15 shows the structure of a neural network and the connect paths to and from one hidden layer neuron.

The total input to the hidden-layer neuron  $j$ ,  $U_j$ , is the summation of the weight multiplied by the input value,  $x_i$ , for each connection path:

$$U_j = W_{j0} + \sum_{i=1}^N W_{ji} \times x_i \quad (\text{Eq 1})$$

where  $N$  is the number of inputs, and  $W_{j0}$  is the bias of the neuron, which is simply another weight in the network. The bias allows the neuron to have an extra degree of freedom to adjust to allow the input-output relationship to be learned accurately during training. The output from the hidden-layer neuron,  $V_j$ , is given by:

$$V_j = f(U_j) \quad (\text{Eq 2})$$

where  $f$  is the activation function. It has also been shown that for the hidden neurons, a sigmoidal activation function, or any other continuous, monotonically increasing, and bounded activation function, is necessary to model the continuous output function (Ref 18). However, a simple linear activation function with a slope of one is sufficient for the output neurons. With these two activation functions, a given output,  $y_k$ , based on the inputs,  $x_i$ , and the connection weights is given by:

$$y_k = \sum_{j=1}^J \{W_{k0} + W_{kj}(W_{j0} + \sum_{i=1}^N W_{ji}x_i)\} \quad (\text{Eq 3})$$

where  $J$  is the total number of hidden neurons.

The most common method to adjust the weights of the connection paths is through the back-propagation algorithm (Ref 19).

As was stated previously, neural networks must first be trained so they are able to generalize, that is, to extract the correct relationship from a finite number of corresponding input-output pairs. During training, a number of input-output pairs,  $Q$ , are given to the network, and the weights of the connection paths are adjusted. The goal of this “learning” is to get the outputs,  $y_k$ , that are calculated using the weights of the neural network as close as possible to the desired output patterns,  $d_k$ , for the training examples. A measure of how well the neural network achieves this goal is the mean square error (MSE) of the process, given by:

$$\text{MSE} = \frac{1}{Q \times K} \times \sum_{q=1}^Q \sum_{k=1}^K [d_k(q) - y_k(q)]^2 \quad (\text{Eq 4})$$

where  $K$  is the total number of outputs.

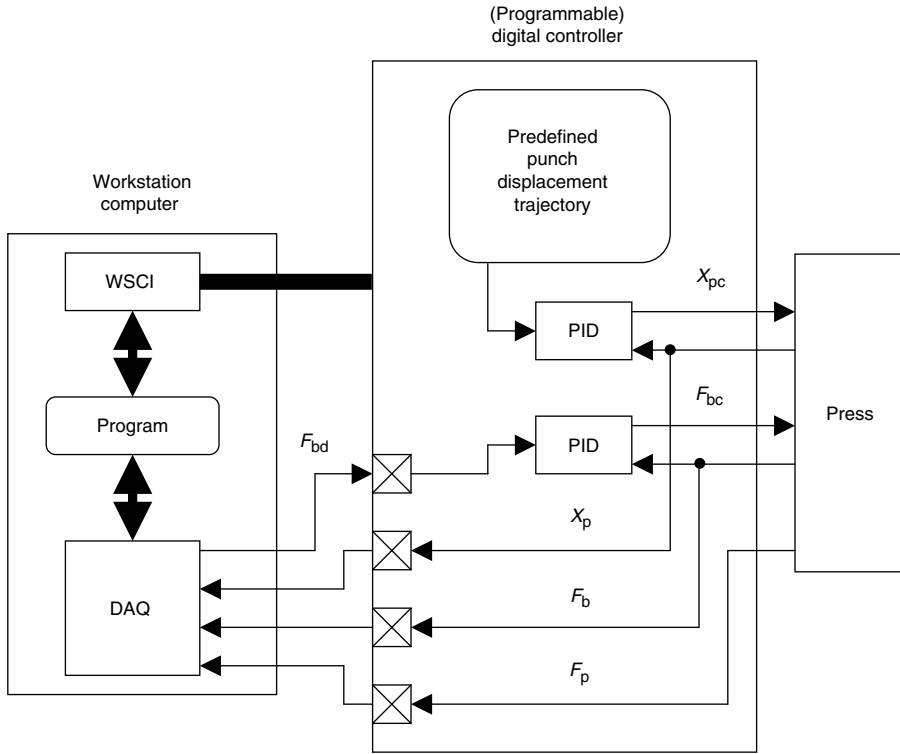

Fig. 10 Implementation of process control in the press. See text for details.

Fig. 11 Punch force plots using process control and a reference punch force ( $F_p$ ) trajectory

**Implementation.** The control strategy is to let the drawing process start as an open-loop system until punch depth reaches 20 mm (0.8 in.). By then, a neural network will analyze the collected punch force data and provide two outputs: when to change the binder force, and how much the new binder force will be. The forming process proceeds with these two new instructions. Notice that there is no interruption of the forming process, because the calculation time needed for the neural network is negligible.

The first step to implement a neural network is to generate training data. In this example, the desired springback angle range was set to between 10 and 12°, and the training data in Tables 2 and 3 were generated via the trial-and-error approach. This springback angle range was chosen based on the capacity of the hydraulic press used in the experiment; that is, a higher binder force value would be required in order to reduce the springback angle further. A total of 20 training sets were generated, a combination of five materials with four lubricant conditions. See Table 2 for a list of all the training data, Table 3 for the obtained springback angles, and Table 4 for material constants.

Based on the training data of Table 2, the gains of a neural network were determined using the MATLAB neural network toolbox. A two-layer neural network was used with a sigmoidal activation function between the input and hidden layers and a linear activation function between the hidden and output layers. To determine the optimal number of hidden neurons to use in the neural network, a validation study was conducted. First, the training data were separated into two groups of data, a set of sixteen input-output pairs for initially training the neural network and a set of four examples for validation of the training process. These four training input-

output pairs are shown in parentheses in Tables 2 and 3. The validation study procedure is as follows. First, neural networks with varying numbers of hidden neurons are trained with the sixteen input-output pairs. Then, the inputs from the four validation examples are “fedforward;” that is the trained neural network is exposed to the input values to obtain outputs. Mean square errors are then calculated based on the difference in the output values calculated by the network and the known output data for the four validation examples. With too few hidden layer neurons, the input-output relationship would not be learned adequately, leading to a high mean square error. With too many hidden layer neurons, the neural network would be oversensitive and not adapt well to new inputs not seen during training, also leading to high mean square error. For the network, three hidden neurons were determined to be optimal to balance these two conflicting constraints.

Now that the structure for the neural network was established, that is, three inputs, three neurons at the hidden layer, and two outputs, the neural network was retrained with all twenty input and output pairs. The weights and biases were then extracted from the MATLAB neural network software and reconstructed using algebraic equations in a LabVIEW (Ref 20) process control program.

**Experimental Results.** With the neural network calculations now embedded in a LabVIEW process control program, experiments were conducted. Various materials with different friction conditions were formed. Curve fitting of the punch force trajectory was performed after 20 mm (0.8 in.) of forming, and three inputs from this curve fit were then used as inputs in the neural network equations to determine the higher binder force (HBF) and percentage of total punch

displacement (PD%) for controlling the springback angle. The neural network was able to determine the stepped binder force trajectory to keep springback within a reasonable range when faced with the same material and friction conditions used to train the network (Table 5). This verifies that the neural network learned the relationship of the training data well. However, in order to show that the generalized relationship between springback angle and material and process parameters is captured in the neural network, types of steel and friction condition not seen by the neural network during training were also formed. When a generic steel was formed with no lubricant, a EG250B steel with a synthetic lubrication, and EGCR3 and HDGCR3 with excessive mineral oil applied (20 mL), the neural network predicted reasonable values of HBF and PD% to produce springback only slightly outside the desired range (Table 5). If these materials and friction conditions were used in the training process as well, better results would have been obtained.

Without the neural network, the springback for the various material and friction conditions in these experiments varied from 4° to 30° for the same range of binder forces, 160 to 330 kN (18 to 37 tonf). The central processing unit was able to perform the neural network calculations fast enough to change to the HBF at the specified PD%. The time required to calculate the outputs of the neural network was 5 ms on the 233 Hz Pentium microprocessor. The network also provided good results when the tooling was disassembled and reassembled. This was done to demonstrate that the network could be used in industry where there are frequent tooling changeovers.

This example demonstrates the benefits of using neural networks to control springback in sheet metal forming. The steel channel forming process was reasonably immune to inevitable variations in process and material parameters, thus producing more consistent sheet metal products. For more details, please refer to Ref 15.

**Example 2: Control Systems for Steel Rolling.** Another application of feedback control in the metal forming industry is in steel rolling mills. The control objective in this application is to maintain the thickness of the rolled steel sheet. Steel rolling mills may be hot or cold, but in both cases, the steel is rolled into sheets by large rolls that apply pressure on the metal as it rolls through. The thickness of the rolled steel depends on the force applied on it by the rolls and

**Fig. 12** Modulation of binder force to follow a predetermined punch force profile

**Fig. 13** Tooling geometry and springback angle in a plane-strain channel forming (only half-model is shown)

the feed rate, which is dependent on the speed of the rolls.

One of the challenges in designing a control system to minimize the thickness variation of the rolled steel is that measuring the thickness of the steel as it passes through the rolls is very difficult. Instead, piezoelectric sensors are typically used to measure the force applied by the rolls on the steel, and the resulting thickness is estimated by developing models of the effective stiffness of the system. The difference between the desired thickness and the estimated thickness is used as the error signal to the controller. The controller

typically drives two actuators, namely, a hydraulic actuator that regulates the force applied by the roll and a motor that regulates the speed of the roll. Thus, this control system can be viewed as a single-input, dual-output system. The dynamics of the system are complex, because they involve the hydraulic dynamics of the hydraulic actuator, the electrical dynamics of the motor, and the mechanical dynamics of the rolling process. In addition, in hot rolling mills, an additional control variable is the rate of flow of coolant, and, if this is the case, the thermodynamics of the process also come into play.

Several disturbances also present problems; for example, there can be variations in the properties of the steel, eccentricities in the rolls, and fluctuations in drive voltage supplies. There are also several nonlinear effects, such as backlash in the gears in the drives and flow-rate saturation limits on the hydraulic actuators.

Several control strategies ranging from simple PID controllers to intelligent adaptive controllers have been applied to the problem of controlling thickness in steel rolling mills.

**Example 3: Control Systems for Resistance Spot Welding.**

Resistance spot welding (RSW) is a major joining operation that is used extensively in the automotive, appliance, and office furniture industries to fabricate sheet metal assemblies and components. The RSW technique involves creating coalescence between workpieces by melting the material between the electrodes through the application of a resistive electric circuit. The quality of a weld depends on the volume of melted material, which depends on the amount of generated heat.

Process variables include welding current, pressure applied on electrode, weld time, material type, and workpiece thickness. The major advantages of RSW include high speed of application, adaptability for automation, low cost, and suitability for high-volume production. A major disadvantage of RSW is the inconsistency of its welds that result from the

complexity of the basic process as well as other sources of variation (material, thickness, coating, surface roughness, electrode wear, current, etc). Inconsistent weld quality drives up cost and therefore demonstrates the need for effective control of the welding process. Controlling the process means controlling the amount of heat generated by the electrical resistance to current and used for melting the workpiece contact interface. The heat developed can be computed from:

$$H = I^2 R t$$

where  $H$  is the heat (joules),  $I$  is the current passing through workpieces (amperes),  $R$  is the electrical resistance in the workpieces (ohms), and  $t$  is the time of current passage (seconds).

The electrical resistance varies with location along the electrodes/workpieces setup, with the highest resistance at the workpieces interface. It has been shown that taking resistance changes during welding as a feedback parameter to control weld quality is not viable in spite of the fact that resistance is an important and measurable parameter (Ref 21). Electrode displacement caused by thermal expansion associated with nugget formation and growth during welding was found to be a reliable feedback signal for predicting and controlling weld quality. Many control systems were developed so that the actual electrode displacement tracks an optimal electrode displacement trajectory (reference trajectory). In such control systems, the welding current undergoes modulation to compensate for

the process variation in order to follow the reference electrode displacement trajectory. The implementation of this tracking control strategy requires modeling of the welding process, designing an appropriate process controller, and determination of an optimal reference trajectory for each material and joint geometry. A key disadvantage for using tracking control strategies to achieve consistent weld quality is that each controller can only be used to weld a specific joint, and that limits automation of the welding process. Efforts are underway to develop intelligent control systems such as fuzzy logic and neural network to achieve effective control and automation of the resistance spot welding process.

## Conclusions

In this article, the basic concepts of feedback process control have been introduced, and various examples of control system applications have been described. The examples have shown that appropriate control strategies increase the robustness of the processes by eliminating process sensitivity to system variations and external disturbances. Results have shown that the implementation of effective process control stabilized the manufacturing process and produced consistent part quality every time.

The use of effective control design, along with high-performance hardware and software for controller implementation, allows the use of

feedback process control for manufacturing processes to improve part quality and consistency. The implementation of this technology requires a one-time capital cost, but the benefits from improved production efficiency are recurring. The application of feedback control in the manufacturing environment will continue to increase because of the increasing demand for better quality and more consistent products.

# Rapid Prototyping for Sheet-Metal Forming

Lotta Lamminen Vihtonen, Helsinki University of Technology, Finland  
Boel Wadman, IVF, Sweden  
Torgeir Svinning, SINTEF, Norway  
Rein Küttner, Tallinn Technical University, Estonia

RAPID PROTOTYPING (RP) techniques in the sheet-metal forming industry have been developed to meet the needs to quickly test the form and fit of new sheet-metal products on a prototype basis as well as for production runs characterized by small lot sizes. Rapid prototyping methods often place high demands on the production system as a whole. High flexibility, fast changeover, and short decision times are important. In addition, apart from adapting a manufacturing facility to low-volume production, the right forming process must be chosen. In general, considerations that are key to the design process for efficient low-volume production include:

- Reduced lead time for each product and reduced changeover time between products
- Reduced time and cost for the development and fabrication of tooling
- Flexible production units and production lines
- Reduced time between different products by using flexible tooling, for example, incremental forming or fluid forming
- Flexible and common control and materials handling system for each unit and for the whole production line

This article provides an overview of some of the technologies used for RP and low-volume production of sheet-metal parts. The discussion is summarized in two major sections, the first dealing with low-cost tooling, processing techniques, and equipment and the second with various aspects of incremental sheet forming.

## Low-Cost Tooling and Flexible Sheet-Forming Processes

**Low-Cost Tooling for Low-Volume Production.** Low-cost tool materials and shortened tooling-manufacturing times can reduce the overall cost of tooling. Tool materials can be cast iron, aluminum, and zinc alloys with high

machinability. For prototypes and mild steel, polymers and wood can also be used as tooling materials.

Rapid tool-manufacturing methods include:

- *Laminated tools:* laser or precision cut layers that are joined by bolting and/or adhesives
- *Concrete or polymeric substrates* with plated nickel surface coatings (Fig. 1)
- *Direct fabrication methods:* Laser sintering, high-speed milling, casting

Efficient systems for the design and three-dimensional (3-D) modeling of tools also are important.

**Multiprocess Equipment.** Most sheet-metal products are subject to processing steps in addition to the forming operation. This may include blanking/cutting before or after forming, various joining methods, processes for making holes, and so forth. For high-volume production, such operations may be performed with equipment included in the production line, for example, welding cells, flying saws, hole punching, or machining operations of various kinds. For low-volume production, on the other hand, one often has to rely on equipment that is flexible enough to be reprogrammed according to a changing

**Fig. 1** Low-volume tooling produced by the rapid manufacturing method metal copy. Courtesy of Protolab AB, Sweden

product spectrum. The importance of having the same kind of control system for the combined units, that is, the production line, is obvious. Another possibility is where the production unit in itself is capable of performing various tasks.

One example of flexible manufacturing and associated equipment is laser cutting and forming (Fig. 2). A CO<sub>2</sub>-laser can be used both to cut the sheet material and to form simple geometries. The heat induced by the laser beam bends the sheet to the calculated geometry. Metals with low thermal conductivity, for example, stainless steels, are more easily deformed. Both thin and thick gages can be formed. The method was originally used for tube bending in the ship-building industry. Principal recent developments in this area include models to predict the heating passes needed to produce the desired formed geometry. Laser optics to form circular and double-curved shapes have also been developed recently. Another process similar to laser forming, in which heat is used to generate internal stresses in the material and thus cause the sheet to bend, is plasma jet forming. For more information on these technologies, see the article "Thermal Forming of Sheet and Plate" in this Volume.

(a) Different modes of multipoint forming can be either passive or produces an active pressure toward the stamp. (b) Flexible multipoint forming of 16 mm (0.63 in.) stainless steel sheet. Courtesy of Unformtechnik Stade GmbH, Germany

Another flexible method with which several process steps can be included in the same line is roll forming. Using “start-stop” rolls or “flying tools,” clinching, punching, and welding can also be performed at different stages of sequential bending operations. Special rolls may also be applied to modify the surface of the profile, for example, by “imprinting” a specified pattern. Tools for roll forming have a lower cost than complicated press tools, but a higher cost than press-brake tools, which makes the method applicable for medium-size production lots of beams and elongated panels.

**Flexible Forming Media.** Reducing the number of stamping dies is another way of lowering part cost. For example, advanced flexible punch-and-die methods based on multipoint methods have been developed in China. Different modes of multipoint forming are shown in Fig. 3.

In such processes, several hydraulic cylinders work against each other to shape a detail. Early try-outs of the process gave rise to poor surface finish, which was ameliorated to some extent by the use of an intermediate sheet.

In rubber-pad forming, one of the tools is replaced by a thick rubber mat that deforms during pressing. This is used, for example, for coining and embossing, in which only a small amount of metal is needed to flow into the formed region. In related hydroforming methods, a fluid replaces one of the two press tools. A method frequently used for prototypes is fluid-cell forming (Fig. 4) or flex forming. One rigid tool is used for simple geometries. The blank is formed between the tool and a rubber diaphragm that is pressurized with castor oil up to 1600 bar. The blank is not in contact with the forming oil. The process characteristics, geometric limitations, and selection criteria are:

*Process characteristics:*

- Large details, up to maximum press table size: 1.3×2.5 m (4.3×8.2 ft)

**Fig. 4** Fluid-cell forming of detail with undercut. (a, b) The sheet (1) is pressed toward a rigid tool by a rubber membrane (2) filled with castor oil (3). (c) Membrane returns to original position after forming

- Surface roughness: depending on tool surface finish,  $R_a = 6 \mu\text{m}$  is normal
- Cycle time: Approximately 5 min, independent of product size. (If several tools exist, 2 to 5 smaller products can be formed simultaneously.)
- Time from computer-aided design (CAD) to product: ~2 to 4 weeks
- Tool cost: depending on size, \$2000 to \$5000
- Changeover time between products: 1 to 8 h, depending on tool complexity
- Cost of production line: \$70K to \$1M (U.S. dollars, 2006)

*Geometric limitations:*

- Inner (concave) radii are defined by the forming pressure and cannot reach smaller values than the sheet thickness
- The corner radii and edge radii are dependent on the product height. The lower the product height, the smaller the radii that can be formed.

*Selection criteria:*

- Low-volume production in which lower tool cost can balance longer cycle time
- Large products with low height and small radii
- Small radii products made from thin-gage mild steels

- Double-curved shapes and flat details that need high-pressure forming to obtain lower springback
- Negative radii—formed if the tool can be divided and withdrawn from the detail

## Incremental Forming

Incremental forming of sheet metal comprises the use of rollers, pins, and so forth to form small, local regions of sheet material in an incremental fashion until the entire part is made (Fig. 5). The literature on sheet-metal forming is relatively large. However, only a limited amount of work has focused on incremental sheet forming. Most of the efforts in this area have been conducted in Japan and South Korea.

## Background

**Experimental investigations** of incremental sheet forming have focused on the various aspects of deformation and deformation uniformity and formability. Most authors have used standard three-axis milling machines to investigate incremental forming.

Sheet-metal bulging with a spherical roller is considered in Ref 2 to 5, hammering in Ref 6

and 7, spinning in Ref 8 and 9, peen forming in Ref 10, and bulging with an elastic tool in Ref 11. Incremental forming of sheet metal with a single-point tool is studied in Ref 12 to 14. Reflective surfaces of automobile headlights were prototyped in Ref 14. A new flexible sheet-metal forming system for fabricating micro-three-dimensional structures of metallic foil materials of less than 10 nm in thickness has been developed (Ref 15). Iseki and Naganawa studied multistage forming using special tooling for straightening after incremental forming of walls (Fig. 6) and the bottom surfaces (Fig. 7) of formed parts.

Sheet formability during incremental forming has also been investigated (Ref 16–18). In Ref 16, for example, a forming tool containing a freely rotating ball was used. The results observed in the tests were quantified via grid measurement and finite-element method (FEM) analysis. A unique forming-limit curve (FLC) was obtained. It was found that the FLC is very different from that pertaining to conventional forming. The FLC appears to be a straight line with a negative slope in the positive region of minor strain. It was also observed that cracks during incremental forming occur mostly at the corners due to greater deformation in these regions.

The effects of process parameters (tool size, feed rate, plastic anisotropy) on formability during incremental forming have also been determined (Ref 17). The formability of aluminum sheet under various forming conditions is considered in Ref 18. Complex shapes (e.g., octagonal cones, stepped shapes) were produced with the proposed technique.

Different die technologies and dieless technologies for setup and small lot sizes are compared in Ref 19. The principles and features of recently developed incremental forming

processes have also been summarized (Ref 20, 21). In Ref 21, special attention is paid to spinning of cones and flow forming.

**Analytical Modeling of Incremental Forming.** Analyses of incremental forming have ranged from relatively simple analytical techniques to detailed FEM analyses.

An approximate plane-strain deformation analysis for the incremental bulging of sheet metal using a spherical roller was developed and applied to describe the bulge forming of non-symmetric shallow shells (Ref 2). In the model, it was assumed that the sheet metal in contact with the roller stretches uniformly. Friction at the interface between the tool and sheet, plastic anisotropy, and the Bauschinger effect were neglected. Closed-form expressions for the uniform strains and the shape of the deformed shell were developed. The tensile force was determined from the condition that the undeformed part is rigidly moved due to the stiffness of the shell. The approximate analytical results were verified by FEM analysis and validated by experiments.

Vertical-wall-surface forming of rectangular shells using multistage incremental forming has also been investigated (Ref 3). A method for calculating the approximate distribution of thickness strain and the maximum bulging height was proposed using a plane-strain deformation model with a constant strain gradient.

A relationship between the blank and its formed configuration under conditions of uniform straining was obtained in Ref 1. The following characteristics of the incremental forming process were assumed:

- The sheet is formed according to a given locus.
- The deformation of the sheet is point-by-point.
- The deformation during every step is small.

Two reasons leading to the unevenness of the wall thickness distribution were discussed in detail:

- Because of springback, the deformation at the center of the blank is smaller than that at the boundary when there is the same value of the deformation.
- For elements of the blank lying at equal distances from the center of the sheet, the portions formed later in the process undergo a certain displacement and strain hardening before the tool bulges them. Thus, these portions develop smaller plastic deformation for the same value of displacement.

The solution for both of these problems was also proposed in Ref 1, that is:

- Because the boundary of the sheet is fixed and the center is free, the stiffness of the boundary is large and the stiffness of the center is small. Therefore, incremental forming steps should be performed in the sequence from low stiffness areas to high stiffness areas. Thus, the plastic deformation of the center can be increased and the plastic deformation of the boundary can be decreased, which reduces the degree of evenness of the deformation.
- Deformation increments should be small, which makes the sheet approach the final shape of the part integrally and evenly. Thus, the strain hardening of the areas formed later in the sequence can be decreased. In practice, the sequence of forming increments should be alternated; that is, the area that is formed first in a given incremental step should be formed later during the next incremental step.

### FEM Simulation of Incremental Forming.

As described previously, it is difficult to predict the thickness-strain distribution in a part after the accumulation of numerous incremental deformation passes. One option is to calculate the thickness strain during the whole deformation process by using FEM analysis. However, FEM has some difficulties when applied to the incremental sheet-metal forming process. The most critical problem is the large number of calculation steps. Compared with conventional sheet-metal forming processes, incremental forming has a simple deformation mechanism, but the deformation path of its moving tool is much longer. If the entire process has to be analyzed using FEM, therefore, very long computation times may be required (Ref 22).

A simplified FEM model of incremental forming was developed assuming that all deformation occurs only by shear (Ref 22). The intermediate shape was determined from the predicted thickness strain to distribute the deformation uniformly. The proposed method was applied for the analysis of an ellipsoidal cup and a clover cup.

In their work, Kim and Park (Ref 17, 18) used the commercial FEM code PAM-STAMP (Ref 23) for the analysis of incremental forming. PAM-STAMP is a dynamic explicit program that

was developed specifically for the simulation of sheet-metal forming processes. It was used to analyze the deformation that occurs in the straight-groove test. The results of this analysis provided enough information to understand observed trends (Ref 17). The model considered the tool, the blankholder, the sheet (blank), and the die, which were all modeled using 3-D shell elements. The tool was moved stepwise vertically by 0.5 mm (0.02 in.). After each vertical step, it was translated on a horizontal plane along rectangular path. Thickness distributions and strains were obtained from the analysis.

In other work, Iseki (Ref 24) used ABAQUS (Ref 25) and 3-D shell elements to simulate the incremental bulging process. A hemispherical tool was moved stepwise vertically. After each vertical step, it moved on a horizontal plane along a rectangular path. Finite-element method predictions were in good agreement with experimental measurements.

### Dieless NC Forming

Dieless NC forming is a numerically controlled incremental-forming process developed in Japan that can cold form various materials into complex shapes. The method allows forming without large and expensive dies, using only a simple support tool under the formed piece. This makes the method very cost effective. The technique was developed to meet the needs of the automotive industry as an alternative manufacturing method for small production lot sizes and rapid prototyping. It has been commercialized by the Japanese company Amino Corporation.

**Principle of Operation.** In dieless NC forming, the geometry of the sheet-metal part is converted from CAD data through a computer-aided manufacturing (CAM) system to NC data. These data are then downloaded to a three-axis CNC machine (Fig. 8), which drives the forming tooling. The blank is clamped to a square blankholder ("work holder") such that there is no draw-in from the binders. The so-called Z-tool moves in the Z (vertical) and Y directions; the work holder is counterbalanced to the vertical movement of the tool and is translated in the vertical direction according to the descent of the Z-tool and along the X and Y directions. Some machines only allow motion along the

**Fig. 10** Dieless NC forming process

X direction. The X and Y plane movements are synchronized with the tool motion to produce the desired form on the sheet.

In practice, a support tool is placed under the work holder and the sheet-metal blank is formed against the support tool (Fig. 9). The moving Z-tool slides over the surface of the blank and presses it into the desired form via stretching and bending. Forming starts on the top of the piece, under which the support tool is placed. The Z-tool makes a round path around the support tool and, after one round, is lowered at a defined pitch and continues forming. The tool path and the vertical pitch are defined by special conversion software based on the CAD model of the product. The tool changes its direction of motion after each round to prevent twisting of material around the Z-axis of the product. The actual forming process is illustrated in Fig. 10.

The Z-tool is made of hardened steel, and its tip is spherical. The minimum diameter of the tool is 6 mm (0.24 in.). The tool diameter affects surface quality; larger diameters result in smoother surface finishes and tool marks are smaller.

The forming force depends on the sheet thickness and material. The force has to exceed the yield strength to create plastic deformation. The forming process requires lubrication on the surface of the sheet. Lubrication decreases the friction between the tool and the sheet and absorbs the heat caused by deformation. The amount of the lubricant depends on the material and thickness of the sheet. Forming of stainless steel and thick sheets requires more lubricant than thick aluminum sheets.

**Limitations.** Dieless NC forming is suitable for one-piece and low-volume production. It can also be used as a prototyping method for sheet-metal products produced in moderate volumes. Maximum production capacity of a dieless NC forming machine is approximately 500 pieces/month, varying widely depending on the size and complexity of the formed product. The method is slow compared to conventional sheet-metal forming operations such as deep drawing and thus is not competitive with such techniques under full-scale production conditions. Process limitations are described in more detail as follows.

**Part Geometry.** Dieless NC forming is a suitable method for producing complicated three-dimensional parts. The product geometry is essentially unrestricted except for a few limitations depending on sheet thickness and the equipment used. For example, the tool size defines the minimum rounding radius, which is half of the tool diameter. The tool size depends on the sheet thickness, because small-diameter tools are not strong enough to impart the required forming forces for thick sheets. At present, the smallest tools used in the process have a diameter of 6 mm (0.24 in.); thus, the minimum rounding radius is 3 mm (0.12 in.). However, the machine manufacturer recommends that the smallest rounding radius be 5 mm (0.2 in.).

A second part limitation arises because the forming tool operates only in the Z-direction. This makes inward bent forms impossible. The wall angle is limited by the sheet thickness. The more the sheet is stretched and bent, the more it thins (Fig. 11). The material formability affects the minimum wall angle as well. Hardened sheet tends to undergo shear failure if the wall angle is too steep. Forming tests have shown that the minimum wall angle is approximately 25° for steel, 20° for pure aluminum, and 30 to 35° for heat treatable aluminum alloys.

The product geometry also defines the need and complexity of the support tool. Simple support tools can be used when the part walls do not include horizontal surfaces. In such cases, the sheet can be supported at the highest point of the product, and the walls can be formed without any extra support. Examples of such products and support tooling are shown in Fig. 12.

If there are planar surfaces that have to be accurate, the blank has to be supported from

below. The Z-tool can be programmed to form a planar surface also without a support tool beneath, but this easily results in sloping. When forming proceeds to the point at which the wall bends again, the sheet bends instead of stretches and the planar surface twists if the edge is not supported. Figure 13 shows a bathtub formed with dieless NC forming and the support tool used in the forming. All of the planar surfaces and rounding radii are supported while the rest of the walls are formed freely. The more complex the part is, the more detailed the support tool has to be. In some cases, the support tool may be as detailed as the final product.

**Product Size.** The maximum product size is determined by the machine size. There are five different sizes of machines for research and production use. The technical characteristics of these machines are summarized in Table 1.

The maximum sheet thickness is different for each machine. The critical design factor is the force needed for forming. Because flow stress varies according to the material used, the forming force and thus the maximum sheet thickness depends on the specific material and the machine used. For example, possible material thicknesses range from 0.5 to 2 mm (0.02 to 0.08 in.) for stainless steel and 0.5 to 4 mm (0.02 to 0.16 in.) for aluminum (Table 1).

Dieless NC forming enables greater effective drawing ratios than conventional deep drawing. For dieless NC forming, the forming path is different, and tooling geometry does not restrict the material flow as with conventional tooling. When forming starts from the top of the piece

and the center of the sheet, the material stretches and moves away from the tool as the forming proceeds. This enables greater effective drawing ratios.

**Surface Quality.** The Z-tool leaves marks on the formed surface during each forming iteration. The tool marks can be decreased by using tools with large diameter and by decreasing the forming pitch. However, smaller pitch leads to longer forming time, so there is a trade-off between production time and surface quality. Furthermore, if the pitch is smaller than 0.01 mm (0.0004 in.), the material is formed several times at each same spot, and it will strain harden and possibly tear. Strain hardening also increases the local strength of the sheet, which can lead to twisting.

Large, slightly curved surfaces are difficult to form. Tool marks are clear, because the horizontal movement for each pitch is large and the curve is very gentle. Tool marks can be prevented by using a sacrificial sheet on the top of the actual workpiece during the forming process. By this means, tool marks are developed on the sacrificial sheet, which in turn imparts the geometry to the actual sheet below. The geometry thus produced is not as accurate as it would be with direct tool contact, but the surface quality is better. The actual sheet can then be formed again without using a sacrificial sheet in order to sharpen the details in the product.

Hirt, Junk, and Wituski (Ref 26) have quantified how forming affects surface roughness. The forming process smooths the surface on the forming side of the product, but the surface roughness on the other side of the sheet increases correspondingly. As the tool diameter increases, the surface roughness decreases. The surface roughness can also be decreased by changing the forming direction on each round and decreasing the forming pitch. Inasmuch as all portions of a blank are not formed equally, some regions staying completely unformed, the surface roughness is not constant over the product surface. Planar surfaces are always undeformed; thus, the surface roughness in such regions remains the same as the surface roughness of the original material. Steep wall angles require more forming and small pitch; hence, the surface roughness is decreased during the forming.

**Materials.** Dieless NC forming has been tested with sheets of carbon steels, alloy steels,

**Fig. 11** Correlation between sheet thinning and bending. The final thickness ( $t_f$ ) depends on initial thickness ( $t_0$ ) and bending angle ( $\theta$ ). Source: Ref 26

Maximum sheet thickness, mm					
Stainless steel	0.5–1	0.5–1	0.5–2	0.5–2	0.5–2
Aluminum	0.5–3	0.5–3	0.5–4	0.5–4	0.5–4

stainless steels, aluminum alloys, titanium, and coated steels. The best results with regard to control of final geometry and springback were achieved with deep-drawing steels. Alloy steels are also easy to form, but they exhibit large springback because of their high strengths. Stainless steels require large forming forces, which lead to thinner sheets than when forming mild (carbon) steels. Stainless steels also exhibit large springback, and parts tend to twist during the forming process. In addition, stainless steel requires good lubrication during forming, and the forming speed has to remain low.

The formability of aluminum depends on the specific alloy used. Unalloyed aluminum (designation 1000 and 1100-O) is easy to form. Aluminum alloys in the 6xxx series, which contain magnesium and silicon, have poor formability and exhibit large springback. Therefore, pure aluminum is recommended for forming if it is suitable for the intended product.

Titanium heats up during forming and tends to blister. Forming coated sheets is difficult, because the coating comes off easily under the forming tool. If the sheet can be formed on the reverse side, the coating on the face side remains untouched.

It is also possible to form perforated steel using dieless NC forming. Here, the minimum wall clearance is approximately  $45^\circ$ . The holes stretch as the sheet stretches. However, when the clearance angle and rounding radii are kept large, the sheet does not tear during forming.

**Economics of Incremental Sheet-Metal Forming.** Incremental sheet forming costs have been compared with the cost of deep drawing for the simple example shown in Fig. 14. The cost comparison between these methods was based on the following relation (Ref 27, 28):

$$C = VC_{mv} + P_c R_c$$

in which  $C_{mv}$  is the cost of material per unit volume,  $V$  is the volume of material input to the process,  $P_c$  is the basic processing cost for an

ideal part, and  $R_c$  is the cost coefficient for the part design that takes into account shape complexity, surface finish, and tolerances.

For the present example, the cost of material is equal for deep drawing and incremental forming and can thus be disregarded in the calculations. The basic processing cost is given by:

$$P_c = aT$$

where  $a$  is the cost of operating a specific process, including the cost of the machine and its maintenance, labor, and overhead, and  $T$  is the cycle time.

To calculate the cost of incremental forming for the example part, two different sets of processing parameters were examined, one set from experimental work done at the University of Saarland and the second set recommended by the Amino Corporation. The first set of parameters comprised a horizontal forming speed of 15 m/min (50 ft/min), vertical feed of 0.2 mm/step (0.08 in./step), and total length of the forming path of 1465 m (0.9 mi). The second set consisted of a horizontal forming speed of 30 m/min (98 ft/min), vertical feed of 0.5 mm/step (0.02 in.), and total length of the forming path of 585 m (1920 ft).

In approximate numbers, the cost of setting up and NC programming was \$60 in both cases. The cost of deep-drawing dies was estimated to be \$16,000. According to the chosen processing parameters, the unit price per piece can be calculated. The costs are dependent on the cost of labor, electricity, and other consumable costs that vary in each country. According to the calculations, incremental forming is profitable if the example part is made in a lot size of 1000 parts or less (Fig. 15). If the quantity is greater, deep drawing is more profitable when using the forming parameters recommended by Amino. If the research parameters are used, the break-even point is lower, that is, ~200 parts (Fig. 15).

It should be noted that cost of a production method is also highly dependent on product

geometry and can vary a great deal. The previous calculation is an example and can be used as general reference, but it should not necessarily be applied to other parts without additional calculations. Nevertheless, Hirt, Ames, and Bambach (Ref 29) have estimated the economic and environmental aspects of incremental forming and found similar results.

**Variants of Incremental Forming.** Dieless NC forming is one variant of incremental forming. There are a few other related variants as well that are being developed in parallel with dieless NC forming.

**Single-Point Forming.** Dieless NC forming is sometimes called two-point forming because there are two contact points with the sheet, one between the sheet and the forming tool and the other between the sheet and the support tool. In single-point forming, the support tool is eliminated, and only the forming tool is in contact with the sheet. The principle of the method is shown in Fig. 16.

In one of the first investigations of single-point forming, Jeswiet used a three-axis CNC mill together with CAM software to control the shaping tool (Ref 12, 30). The sheet was clamped to a blankholder mounted on the mill bed. The shaping tool was a rounded rod, which was placed in the mill spindle. The blankholder remained stationary as the shaping tool pushed into the sheet, deforming it directly under the tool. During the forming, the tool was lowered in small steps after each round. Initially, Jeswiet used support under the sheet, but as the work progressed, he found that the supporting tool was not necessary. As for two-point forming, the finished part shape was created by computer-controlled tool movements.

**Robot-Assisted Incremental Forming.** Industrial robots can be used to control the forming tool similar to dieless NC forming (Ref 31–34). The process is comparable to, and the forming results are also very similar to, those achieved with dieless NC forming machines. The advantage of industrial robot is the possibility to turn the forming tool and thus access blind edges of parts. Also, many companies already have robots in-house, which makes it easier to take this

Fig. 14 Dimensions (in mm) of part used in process-economics calculations

Fig. 15 Cost comparison diagram for incremental forming and deep drawing

method into use. A robot cell for incremental forming is shown in Fig. 17.

**Incremental Hammering.** Hammering is perhaps the oldest form of sheet-metal forming. The modern method of incremental hammering utilizes computer-controlled robots without a support tool. The sheet-metal blank is attached to a supporting frame, and the forming tool is attached to an industrial robot. The robot punches the sheet into the desired form using a circular forming path, descending a small step for each round. The tool does not touch the sheet while moving in the X-Y directions. This eliminates sheet stretching and twisting during forming, but also affects the surface quality of the product. An experimental incremental hammering setup is shown in Fig. 18.

**Applications.** Dieless NC forming is well suited for producing single pieces as well as small lot sizes. It can also be used in prototyping and the production of spare parts. Forming costs are approximately 5 to 10% of the costs of traditional press forming, but the production speed is also lower. Despite the slower speed, the method is more efficient when producing single parts or small quantities of parts.

When using dieless NC forming for making spare parts, considerable savings are realized because large dies need not be kept in inventory. Die storage is a problem especially in the automotive manufacturing industry, because parts are generally large and the product life cycle is

relatively long. This leads to long storage times and costs. New car models are constantly developed, and the number of dies that must be stored increases.

Dieless NC forming enables the manufacture of different kinds of parts in the same machine without long lead times. The only part-specific component of the machine setup is the support tool, which is easy and quick to change. If the support tool is made of a soft material such as wood or polymer, it is also quick and affordable to manufacture.

TAI Research Center in the Helsinki University of Technology implemented a research project together with Finnish industrial partners in 2002 to assess the suitability of dieless NC forming in a real production environment. The test results showed that part geometry was important when considering the suitability of the method. The test parts in the project were real parts in production; they were not designed specifically for dieless NC forming. This fact affected the forming results. If a part is designed for the manufacturing method, the special requirements of the method can be taken into account, and the final results will be better. When applying the new method directly for an existing part, however, there are generally more difficult shapes and other features that provide challenges for the method. These problems can be avoided by designing the part specifically taking into account the capabilities and limitations of the manufacturing technique.

Unlike automobile manufacture, the manufacture of boats usually comprises low-volume production. The design of the boat (or ship) is determined by its intended use, its seagoing properties, and general characteristics regarding shape and equipment. They are typically made from sheets or plates of various thicknesses,

which are formed and joined, most often by welding. The sheet segments are usually joined to an underlying frame of profiles or plate components and vary in shape from one segment to the next. The combination of flexibility in shape, adaptation to an underlying frame, and joining of adjacent segments represents a major challenge to boat builders. In order to reduce the amount of sizing after forming and distortion after welding due to residual stresses, low-cost, accurate forming methods such as dieless manufacture may be very attractive.

## Conclusions

Low-volume production methods are already in use in many industries. Incremental forming is a new production method for sheet-metal components that brings several new possibilities into the sheet-metal forming field. Geometries that were previously impossible or very expensive to prototype are now possible. Prototypes can also be made from actual production materials.

One incremental-forming process, dieless NC forming, has great potential as a tool in the product development cycle. It can be used for making prototypes, but also individual parts and small lot sizes of parts. A great advantage of such techniques is that prototypes can be made from real materials with real methods and thus be tested as real products. Dieless NC forming can also be combined with other forming methods when manufacturing prototypes or short series of products.

Incremental forming, as any other forming method, has its limitations. Part geometry (e.g., wall angle restrictions, minimum rounding radii) and the number of forming steps are important considerations. On the other hand, process

Fig. 18 Incremental hammering

design variables such as forming path can be chosen to overcome some of the limitations such as wall angle.

HSLA	high-strength, low-alloy (steel)	MDOL	metadynamic recrystallization	RA	reduction of area
$h_T$	heat-transfer coefficient	MDRX	milligram	$R_a$	radii of anticlastic curvature
$H_T$	enthalpy at a given temperature	mg	megagram	$R_c$	critical cavity radius; critical particle size
HV	Vickers (diamond pyramid) hardness	Mg	military	RCR	recrystallization controlled rolling
Hz	hertz	MIL	military standard	$r_d$	tool radius in four-point bend finite-element method model
		MIL-STD	minimum; minute	$R_E$	extrusion ratio
		min	milliliter	Ref	reference
		mL	millimeter	rem	remainder or balance
		mm	material modeling environment	RFQ	request for quotation
$I$	moment of inertia	MME	meganewton	$R_h$	radial distance
$I'$	moment of inertia for distorted cross sections	MN	megapascal	RHR	root height reading
IBR	integral blade and rotor	MPa	multidiscipline process design and optimization	$r_i$	internal specimen radius
ID	inside diameter	MPDO		$r_m$	average of plastic strain anisotropy of the $r$ ratio in 0, 45 and 90 degree directions, where:
IGES	initial graphics exchange specification	$n$	grain growth exponent; strain-hardening exponent		$r_m = \frac{r_0 + 2r_{45} + r_{90}}{4}$
I/M	ingot metallurgy	$N$	number of revolutions	$r_{\max}$	maximum diameter of a specimen deformed to a specific height
in.	inch	$\dot{N}$	twist rate	rms	root mean square
ipm	inches per minute	N	Newton, unit of force	rpm	revolutions per minute
ips	inches per second	NASA	National Aeronautics and Space Administration		
ISO	International Organization for Standardization	NC	numerical control		
		NCEMT	National Center for Excellence in Metalworking Technology		
J	joule	NDE	nondestructive evaluation		
$J$	polar moment of inertia	$N_{EL}$	number of elements used in finite-element analysis model		
JIC	Joint Industry Conference	$N_{IP}$	number of through-thickness integration points for shell or beam element		
		No.	number		
$k$	thermal conductivity; yield strength in pure shear; Boltzmann's constant				
$K$	strength coefficient in uniaxial plastic hardening law	OBI	open-back inclinable (press)		
$K'$	effective strength parameter, taking into account strain/stress state and possible plastic anisotropy	OD	outside diameter		
		OEM	original equipment manufacturer		
		OFHC	oxygen-free high-conductivity		

$s$	engineering stress	VAR	vacuum arc remelted	$\propto$	varies as; is proportional to
SAE	Society of Automotive Engineers	vol%	volume percent	$\alpha$	die half angle; linear coefficient of thermal expansion; flow
SAM	successive approximation methods	$w$	displacement in the $x$ , $y$ , and $z$ directions; width; weight or mass	$\alpha_F$	draft angle of forging
SEM	scanning electron microscopy	$W$	watt	$\alpha_P$	draft angle of preform
SFE	stacking fault energy	$W$	work; width	$\beta$	Searle's parameter ( $\beta = \frac{w^2}{Rt}$ )
SFEM	simplified finite-element method	$W_f$	relative portion of power consumed by friction	$\beta_t$	beta transus temperature
sfm	surface feet per minute	$\dot{W}_i$	relative portion of power consumed by internal deformation	$\dot{\Gamma}$	shear strain rate
SI	Système International d'Unités	WIP	work-in-process	$\gamma$	shear strain; work-hardening coefficient; flow-softening rate; interfacial energy
SLF	slip-line field	$w_p$	width of preform	$\dot{\gamma}$	shear strain rate
SLP	sequential linear programming	WRC	Welding Research Council	$\gamma_f$	shear strain to failure
SM	Sachs (slab) method	$\dot{W}_s$	relative portion of power consumed by shear or redundant work	$\gamma_i$	interfacial energy of particle/matrix interface
SPC	statistical process control	wt%	weight percent	$\gamma_P$	interfacial energy of particle
SPD	severe plastic deformation			$\gamma_{sf}$	surface shear strain at fracture
SPF	superplastic forming			$\Delta$	finite change; volume strain
SPF/DB	superplastic forming/diffusion bonding			$\Delta$	change in quantity, an increment, a range
SQP	sequential quadratic programming	$x$	parameter in Gardiner's equation ( $x = \frac{R\sigma_0}{E't}$ ); also longitudinal coordinate	$\Delta_\phi$	angle through which one end of gage length has been twisted relative to the other
SRX	static recrystallization	$X_{tool}^i$	forming tool position at $i^{th}$ iteration	$\delta$	deformation or elongation; crosshead speed; Kronecker delta
SUS	Saybolt universal second (measure of viscosity)	$y$	coordinate along width direction	$\varepsilon$	true normal strain
$S_v$	austenite interfacial area; total effective interfacial area per unit volume	$\Delta y^i$	the $i^{th}$ displacement correction	$\varepsilon_b$	bending strain
$S_v(GB)$	total effective area per unit volume from the grain-boundary contribution	$z$	thickness coordinate; $z = 0$ at center of thickness	$\varepsilon_e$	elastic strain
$S_v(IPD)$	contribution from intragranular planar defect	$z_0$	location of neutral axis	$\varepsilon_m$	membrane strain
$t$	time; thickness	$z_1^*, z_2^*$	locations of elastic core on tension and compression side	$\varepsilon_p$	plastic strain
T	absolute temperature	$Z$	Zener-Hollomon parameter	$\varepsilon_0$	zero-gage length elongation
$T$	processing temperature; sheet tension force	ZDT	zero-ductility temperature	$\dot{\varepsilon}$	true strain rate
$\bar{T}$	normalized sheet tension, $\frac{T}{w t \sigma_0}$			$\bar{\varepsilon}$	effective strain
TDC	top dead center			$\bar{\varepsilon}$	effective strain rate; mean true strain rate
$T_{def}$	deformation temperature	2-D	two-dimensional	$\bar{\varepsilon}_f$	effective strain at fracture
$t_f$	thickness of forging	3-D	three-dimensional	$\varepsilon_{max}$	maximum tensile strain
TFP	total factor productivity	$^\circ$	degree (angular measure)	$\varepsilon_t$	thickness strain
$T_g$	glass transition temperature	$^\circ C$	temperature, degrees Celsius (centigrade)	$\varepsilon_u$	true strain at maximum load; true uniform strain
$T_{GC}$	grain-coarsening temperature	$^\circ F$	temperature, degrees Fahrenheit	$\varepsilon_w$	width strain
$T_m$	melting temperature	$\div$	divided by	$\varepsilon_0$	circumferential strain
TMP	thermomechanical processing	$=$	equals	$\eta$	coefficient of viscosity; cavity-growth-rate parameter
tonf	tons of force	$\approx$	approximately equals	$\eta_{APP}$	apparent cavity-growth rate
$T_R$	recrystallization temperature	$\neq$	not equal to	$\theta$	$d\sigma/d\varepsilon$ , strain-hardening rate; angle of twist in torsion
TRIP	transformation-induced plasticity	$>$	greater than	$\kappa$	bulk modulus or volumetric modulus of elasticity
$T_{RXN}$	recrystallization stop temperature	$\gg$	much greater than	$\mu$	shear modulus; Coulomb coefficient of friction
$T_S$	solidus temperature	$\geq$	greater than or equal to	$\mu_{in.}$	microinch
tsi	tons per square inch	$\int$	integral of	$\mu m$	micron (micrometer)
TYS	tensile yield strength	$<$	less than	$\mu s$	microsecond
$u$	displacement	$\ll$	much less than	$\nu$	Poisson's ratio
$U$	rate of dislocation generation due to strain hardening; elastic strain energy	$\leq$	less than or equal to	$\pi$	pi (3.14159...)
UB	upper bound	$\pm$	maximum deviation	$\rho$	density of a material; dislocation density
UBET	upper-bound element technique	$\times$	multiplied by; diameters (magnification)	$\Sigma$	summation of
UBM	upper-bound method	$\cdot$	multiplied by	$\sigma$	normal stress component; true stress
UHC	ultrahigh carbon	$/$	per	$\sigma_1 \sigma_2 \sigma_3$	principal stresses
UNS	Unified Numbering System	$\%$	percent	$\bar{\sigma}$	effective or significant true stress; mean stress
UTS	ultimate tensile strength	$+$	plus; in addition to		
$\nu$	Poisson's ratio; velocity	$\sqrt{\quad}$	square root of		
$V$	volume	$\sim$	similar to; approximately		
V	volt				

$\sigma_a$	measured average stress	$\sigma_{\theta\theta}$	circumferential stress	$\Delta, \delta$	delta
$\sigma_c$	flow stress in cavity	$\tau$	shear stress component	$E, \varepsilon$	epsilon
$\sigma_d$	drawing stress	$\tau_i$	interfacial shear (or friction) stress	$Z, \zeta$	zeta
$\sigma_{ep}$	stress at entrance to plane-strain cross section	$\tau_{max}$	maximum shear stress	$H, \eta$	eta
$\sigma_1$	interfacial energy per unit area of boundary	$\tau_o$	shear yield strength	$\Theta, \theta$	theta
$\sigma_m$	hydrostatic or mean principal pressure	$\Phi$	redundant work factor	$I, \iota$	iota
$\sigma_T$	tensile stress	$\phi$	stress-intensification factor; viscosity-pressure coefficient	$K, \kappa$	kappa
$\sigma_{xb}$	back tension	$\dot{\phi}$	shear-strain rate	$\Lambda, \lambda$	lambda
$\sigma_{xf}$	front tension	$\phi_r$	angle between scribe line and torsion axis at failure	$M, \mu$	mu
$\sigma_u$	ultimate tensile strength			$N, \nu$	nu
$\sigma_y$	yield stress			$\Xi, \xi$	xi
$\sigma_0$	flow stress; yield stress; yield strength			$O, o$	Omicron
$\sigma'_0$	yield stress in plane strain; effective yield stress taking into account strain/stress state and possible plastic anisotropy			$\Pi, \pi$	pi
<b>Greek Alphabet</b>				$P, \rho$	rho
		A, $\alpha$	alpha	$\Sigma, \sigma$	sigma
		B, $\beta$	beta	$T, \tau$	tau
		$\Gamma, \gamma$	gamma	$Y, \upsilon$	upsilon
				$\Phi, \phi$	phi
				$X, \chi$	chi
				$\Psi, \psi$	psi
				$\Omega, \omega$	omega

## Officers and Trustees of ASM International (2005–2006)

### Reza Abbaschian

President and Trustee  
University of California Riverside

### Lawrence C. Wagner

Vice President and Trustee  
Texas Instruments

### Bhakta B. Rath

Immediate Past President and Trustee  
U. S. Naval Research Laboratory

### Paul L. Huber

Treasurer and Trustee  
Seco/Warwick Corporation

### Stanley C. Theobald

Secretary and Managing Director  
ASM International

### Trustees

#### Sue S. Baik-Kromalic

Honda of America

#### Christopher C. Berndt

James Cook University

#### Dianne Chong

The Boeing Company

### Roger J. Fabian

Bodycote Thermal Processing

### William E. Frazier

Naval Air Systems Command

### Pradeep Goyal

Pradeep Metals Ltd.

### Richard L. Kennedy

Allvac

### Frederick J. Lisy

Orbital Research Incorporated

### Frederick Edward Schmidt, Jr.

Engineering Systems Inc.

## Members of the ASM Handbook Committee (2005–2006)

### Jeffrey A. Hawk

(Chair 2005–; Member 1997–)  
General Electric Company

### Larry D. Hanke

(Vice Chair 2005–; Member 1994–)  
Material Evaluation and  
Engineering Inc.

### Viola L. Acoff (2005–)

University of Alabama

### David E. Alman (2002–)

U.S. Department of Energy

### Tim Cheek (2004–)

International Truck & Engine  
Corporation

### Lichun Leigh Chen (2002–)

Engineered Materials Solutions

### Craig Clauser (2005–)

Craig Clauser Engineering Consulting Inc.

### William Frazier (2005–)

Naval Air Systems Command

### Lee Gearhart (2005–)

Moog Inc.

### Michael A. Hollis (2003–)

Delphi Corporation

### Kent L. Johnson (1999–)

Engineering Systems Inc.

### Ann Kelly (2004–)

Los Alamos National Laboratory

### Alan T. Male (2003–)

University of Kentucky

### William L. Mankins (1989–)

Metallurgical Services Inc.

### Dana J. Medlin (2005–)

South Dakota School of Mines and  
Technology

### Joseph W. Newkirk (2005–)

Metallurgical Engineering

### Toby Padfield (2004–)

ZF Sachs Automotive of America

### Frederick Edward Schmidt, Jr. (2005–)

Engineering Systems Inc.

### Karl P. Staudhammer (1997–)

Los Alamos National Laboratory

### Kenneth B. Tator (1991–)

KTA-Tator Inc.

### George F. Vander Voort (1997–)

Buehler Ltd.

## Previous Chairs of the ASM Handbook Committee

### R.J. Austin

(1992–1994) (Member 1984–1985)

### L.B. Case

(1931–1933) (Member 1927–1933)

### T.D. Cooper

(1984–1986) (Member 1981–1986)

### C.V. Darragh

(1999–2002) (Member 1989–2005)

### E.O. Dixon

(1952–1954) (Member 1947–1955)

### R.L. Dowdell

(1938–1939) (Member 1935–1939)

### Henry E. Fairman

(2002–2004) (Member 1993–2005)

### M.M. Gauthier

(1997–1998) (Member 1990–2000)

### J.P. Gill

(1937) (Member 1934–1937)

### J.D. Graham

(1966–1968) (Member 1961–1970)

### J.F. Harper

(1923–1926) (Member 1923–1926)

### C.H. Herty, Jr.

(1934–1936) (Member 1930–1936)

### D.D. Huffman

(1986–1990) (Member 1982–2005)

### J.B. Johnson

(1948–1951) (Member 1944–1951)

### L.J. Korb

(1983) (Member 1978–1983)

### R.W.E. Leiter

(1962–1963) (Member 1955–1958,  
1960–1964)

### G.V. Luerssen

(1943–1947) (Member 1942–1947)

### G.N. Maniar

(1979–1980) (Member 1974–1980)

### W.L. Mankins

(1994–1997) (Member 1989–)

### J.L. McCall

(1982) (Member 1977–1982)

### W.J. Merten

(1927–1930) (Member 1923–1933)

### D.L. Olson

(1990–1992) (Member 1982–1988,  
1989–1992)

### N.E. Promisel

(1955–1961) (Member 1954–1963)

### G.J. Shubat

(1973–1975) (Member 1966–1975)

### W.A. Stadtler

(1969–1972) (Member 1962–1972)

### R. Ward

(1976–1978) (Member 1972–1978)

### M.G.H. Wells

(1981) (Member 1976–1981)

### D.J. Wright

(1964–1965) (Member 1959–1967)

# Metric Conversion Guide

This Section is intended as a guide for expressing weights and measures in the Système International d'Unités (SI). The purpose of SI units, developed and maintained by the General Conference of Weights and Measures, is to provide a basis for worldwide standardization of units and measure. For more information on metric conversions, the reader should consult the following references:

- *The International System of Units*, SP 330, 1991, National Institute of Standards and Technology. Order from Superintendent of Documents, U.S. Government Printing Office, Washington, DC 20402-9325
- *Metric Editorial Guide*, 5th ed. (revised), 1993, American National Metric Council, 4340 East West Highway, Suite 401, Bethesda, MD 20814-4411
- "Standard for Use of the International System of Units (SI): The Modern Metric System," IEEE/ASTM SI 10-1997, Institute of Electrical and Electronics Engineers, 345 East 47th Street, New York, NY 10017
- *Guide for the Use of the International System of Units (SI)*, SP 811, 1995, National Institute of Standards and Technology, U.S. Government Printing Office, Washington, DC 20402

## SI prefixes—names and symbols

Exponential expression	Multiplication factor	Prefix	Symbol
$10^{24}$	1 000 000 000 000 000 000 000 000	yotta	Y
$10^{21}$	1 000 000 000 000 000 000 000	zetta	Z
$10^{18}$	1 000 000 000 000 000 000	exa	E
$10^{15}$	1 000 000 000 000 000	peta	P
$10^{12}$	1 000 000 000 000	tera	T
$10^9$	1 000 000 000	giga	G
$10^6$	1 000 000	mega	M
$10^3$	1 000	kilo	k
$10^2$	100	hecto(a)	h
$10^1$	10	deka(a)	da
$10^0$	1	BASE UNIT	
$10^{-1}$	0.1	deci(a)	d
$10^{-2}$	0.01	centi(a)	c
$10^{-3}$	0.001	milli	m
$10^{-6}$	0.000 001	micro	μ
$10^{-9}$	0.000 000 001	nano	n
$10^{-12}$	0.000 000 000 001	pico	p
$10^{-15}$	0.000 000 000 000 001	femto	f
$10^{-18}$	0.000 000 000 000 000 001	atto	a
$10^{-21}$	0.000 000 000 000 000 000 001	zepto	z
$10^{-24}$	0.000 000 000 000 000 000 000 001	yocto	y

(a) Nonpreferred. Prefixes should be selected in steps of  $10^3$  so that the resultant number before the prefix is between 0.1 and 1000. These prefixes should not be used for units of linear measurement, but may be used for higher order units. For example, the linear measurement decimeter is nonpreferred, but square decimeter is acceptable.

## Base, supplementary, and derived SI units

Measure	Unit	Symbol	Measure	Unit	Symbol
<b>Base units</b>			Force	newton	N
Amount of substance	mole	mol	Frequency	hertz	Hz
Electric current	ampere	A	Heat capacity	joule per kelvin	J/K
Length	meter	m	Heat flux density	watt per square meter	W/m <sup>2</sup>
Luminous intensity	candela	cd	Illuminance	lux	lx
Mass	kilogram	kg	Inductance	henry	H
Thermodynamic temperature	kelvin	K	Irradiance	watt per square meter	W/m <sup>2</sup>
Time	second	s	Luminance	candela per square meter	cd/m <sup>2</sup>
<b>Supplementary units</b>			Luminous flux	lumen	lm
Plane angle	radian	rad	Magnetic field strength	ampere per meter	A/m
Solid angle	steradian	sr	Magnetic flux	weber	Wb
<b>Derived units</b>			Magnetic flux density	tesla	T
Absorbed dose	gray	Gy	Molar energy	joule per mole	J/mol
Acceleration	meter per second squared	m/s <sup>2</sup>	Molar entropy	joule per mole kelvin	J/mol · K
Activity (of radionuclides)	becquerel	Bq	Molar heat capacity	joule per mole kelvin	J/mol · K
Angular acceleration	radian per second squared	rad/s <sup>2</sup>	Moment of force	Newton meter	N · m
Angular velocity	radian per second	rad/s	Permeability	henry per meter	H/m
Area	square meter	m <sup>2</sup>	Permittivity	farad per meter	F/m
Capacitance	farad	F	Power, radiant flux	watt	W
Concentration (of amount of substance)	mole per cubic meter	mol/m <sup>3</sup>	Pressure, stress	pascal	Pa
Current density	ampere per square meter	A/m <sup>2</sup>	Quantity of electricity, electric charge	coulomb	C
Density, mass	kilogram per cubic meter	kg/m <sup>3</sup>	Radiance	watt per square meter	W/m <sup>2</sup> · sr
Dose equivalent, dose equivalent index	sievert	Sv		steradian	
Electric charge density	coulomb per cubic meter	C/m <sup>3</sup>	Radiant intensity	watt per steradian	W/sr
Electric conductance	siemens	S	Specific heat capacity	joule per kilogram kelvin	J/kg · K
Electric field strength	volt per meter	V/m	Specific energy	joule per kilogram	J/kg
Electric flux density	coulomb per square meter	C/m <sup>2</sup>	Specific entropy	joule per kilogram kelvin	J/kg · K
Electric potential, potential difference, electromotive force	volt	V	Specific volume	cubic meter per kilogram	m <sup>3</sup> /kg
Electric resistance	ohm	Ω	Surface tension	newton per meter	N/m
Energy, work, quantity of heat	joule	J	Thermal conductivity	watt per meter kelvin	W/m · K
Energy density	joule per cubic meter	J/m <sup>3</sup>	Velocity	meter per second	m/s
Entropy	joule per kelvin	J/K	Viscosity, dynamic	pascal second	Pa · s
			Viscosity, kinematic	square meter per second	m <sup>2</sup> /s
			Volume	cubic meter	m <sup>3</sup>
			Wavenumber	1 per meter	1/m

Aluminum and aluminum alloys are tested frequently for hardness to distinguish between annealed, cold-worked, and heat treated grades. The Rockwell B scale (100 kgf load with a 1.58 mm, or 1/16 in. steel ball indenter) generally is suitable in testing grades that have been precipitation hardened to relatively high strength levels. For softer grades and commercially pure aluminum, hardness testing usually is done with the Rockwell F, E, and H scales. For hardness testing of thin gages of aluminum, the 15T and 30T scales of the Rockwell superficial tester are recommended. Source: ASTM E 140

**Table 2** Approximate equivalent hardness numbers for wrought coppers (>99% Cu, alloys C10200 through C14200)

Vickers hardness No.		Knoop hardness No.		Rockwell superficial hardness No.			Rockwell hardness No.		Rockwell superficial hardness No.			Brinell hardness No.	
				15T scale, 15 kgf, 1/16 in. (1.588 mm) ball, HR15T(a)	15T scale, 15 kgf, 1/16 in. (1.588 mm) ball, HR15T(b)	30T scale, 30 kgf, 1/16 in. (1.588 mm) ball, HR30T(b)	B scale, 100 kgf, 1/16 in. ### D.J. Wright

(1964–1965) (Member 1959–1967)

# Policy on Units of Measure

---

---

By a resolution of its Board of Trustees, ASM International has adopted the practice of publishing data in both metric and customary U.S. units of measure. In preparing this Handbook, the editors have attempted to present data in metric units based primarily on *Système International d'Unités* (SI), with secondary mention of the corresponding values in customary U.S. units. The decision to use SI as the primary system of units was based on the aforementioned resolution of the Board of Trustees and the widespread use of metric units throughout the world.

For the most part, numerical engineering data in the text and in tables are presented in SI-based units with the customary U.S. equivalents in parentheses (text) or adjoining columns (tables). For example, pressure, stress, and strength are shown both in SI units, which are pascals (Pa) with a suitable prefix, and in customary U.S. units, which are pounds per square inch (psi). To save space, large values of psi have been converted to kips per square inch (ksi), where 1 ksi = 1000 psi. The metric tonne ( $\text{kg} \times 10^3$ ) has sometimes been shown in megagrams (Mg). Some strictly scientific data are presented in SI units only.

To clarify some illustrations, only one set of units is presented on artwork. References in the accompanying text to data in the illustrations are presented in both SI-based and customary U.S. units. On graphs and charts, grids corresponding to SI-based units usually appear along the left and bottom edges. Where appropriate, corresponding customary U.S. units appear along the top and right edges.

Data pertaining to a specification published by a specification-writing group may be given in only the units used in that specification or in dual units, depending on the nature of the data. For example, the typical yield strength of steel sheet made to a specification written in customary U.S.

units would be presented in dual units, but the sheet thickness specified in that specification might be presented only in inches.

Data obtained according to standardized test methods for which the standard recommends a particular system of units are presented in the units of that system. Wherever feasible, equivalent units are also presented. Some statistical data may also be presented in only the original units used in the analysis.

Conversions and rounding have been done in accordance with IEEE/ASTM SI-10, with attention given to the number of significant digits in the original data. For example, an annealing temperature of 1570 °F contains three significant digits. In this case, the equivalent temperature would be given as 855 °C; the exact conversion to 854.44 °C would not be appropriate. For an invariant physical phenomenon that occurs at a precise temperature (such as the melting of pure silver), it would be appropriate to report the temperature as 961.93 °C or 1763.5 °F. In some instances (especially in tables and data compilations), temperature values in °C and °F are alternatives rather than conversions.

The policy of units of measure in this Handbook contains several exceptions to strict conformance to IEEE/ASTM SI-10; in each instance, the exception has been made in an effort to improve the clarity of the Handbook. The most notable exception is the use of  $\text{g/cm}^3$  rather than  $\text{kg/m}^3$  as the unit of measure for density (mass per unit volume).

SI practice requires that only one virgule (diagonal) appear in units formed by combination of several basic units. Therefore, all of the units preceding the virgule are in the numerator and all units following the virgule are in the denominator of the expression; no parentheses are required to prevent ambiguity.

# Steel Hardness Conversions

FROM A PRACTICAL STANDPOINT, it is important to be able to convert the results of one type of hardness test into those of a different test. Because a hardness test does not measure a well-defined property of a material and because all the tests in common use are not based on the same type of measurements, it is not surprising that universal hardness conversion relationships have not been developed. Hardness conversions instead are empirical relationships that are defined by conversion tables limited to specific categories of materials. That is, different conversion tables are required for materials with greatly different elastic moduli or with different strain-hardening capacity.

The most reliable hardness-conversion data exist for steel that is harder than 240 HB. The indentation hardness of soft metals depends on the strain-hardening behavior of the material during the test, which in turn depends on the previous degree of strain hardening of the

material before the test. The modulus of elasticity also has been shown to influence conversions at high hardness levels. At low hardness levels, conversions between hardness scales measuring depth and those measuring diameter are likewise influenced by differences in the modulus of elasticity.

Hardness conversions are covered in standards such as SAE J417, "Hardness Tests and Hardness Conversions"; ISO 4964, "Hardness Conversions—Steel"; and ASTM E 140, "Standard Hardness Conversion Tables for Metals." Conversion tables for nickel and high-nickel alloys, cartridge brass, austenitic stainless steel plate and sheet, and copper can be found in ASTM E 140. Recently, ASTM committee E-28 on indentation hardness has developed mathematical conversion formulas based on the conversion-table values found in ASTM E 140. Over 60 conversion formulas are listed in the appendix of ASTM E 140, and these formulas

can be used in place of the tables. A computer is helpful in performing the calculations quickly.

Other hardness conversion formulas for various materials have also been published, and a list of some other conversion formulas is given in Table 1. The standard procedure for reporting converted hardness numbers indicates the measured hardness and test scale in parentheses—for example, 451 HB (48 HRC). The method of conversion (table, formula, or other method) should also be defined.

When making hardness correlations, it is best to consult ASTM E 140. Tables 2 to 5, from ASTM E 140, are for conversion among Rockwell, Brinell, and Vickers hardness for heat treated carbon and alloy steels, almost all constructional alloy steels, and tool steels in the as-forged, annealed, normalized, and quenched and tempered conditions. The tables are also summarized in graphical form in Fig. 1.

**Table 1 Examples of published hardness conversion equations**

Steels		Cemented carbides	
$HB = \frac{7300}{130 - HRB}$	(40–100 HRB)	$HRC = 117.35 - \left( \frac{2.43 \times 10^6}{HV} \right)^{1/2}$	(900–1800 HV)
$HB = \frac{3710}{130 - HRE}$	(30–100 HRE)	$HRA = \frac{211 - \left( \frac{2.43 \times 10^6}{HV} \right)^{1/2}}{1.885}$	(900–1800 HV)
$HB = \frac{1,520,000 - 4500 HRC}{(100 - HRC)^2}$	(<40 HRC)	<b>Rockwell from Knoop for steels</b>	
$HB = \frac{25,000 - 10(57 - HRC)^2}{100 - HRC}$	(40–70 HRC)	$HRC = 64.934 \log HK - 140.38$	(15 gf)
$HRB = 134 - \frac{6700}{HB}$	(±7 HRB, 95% CL)	$HRC = 67.353 \log HK - 144.32$	(25 gf)
$HRC = 119.0 - \left( \frac{2.43 \times 10^6}{HV} \right)^{1/2}$	(240–1040 HV)	$HRC = 71.983 \log HK - 154.28$	(50 gf)
$HRA = 112.3 - \left( \frac{6.85 \times 10^5}{HV} \right)^{1/2}$	(240–1040 HV)	$HRC = 76.572 \log HK - 163.89$	(100 gf)
$HR15N = 117.94 - \left( \frac{5.53 \times 10^5}{HV} \right)^{1/2}$	(240–1040 HV)	$HRC = 79.758 \log HK - 170.92$	(200 gf)
$HR30N = 129.52 - \left( \frac{1.88 \times 10^6}{HV} \right)^{1/2}$	(240–1040 HV)	$HRC = 82.283 \log HK - 176.92$	(300 gf)
$HR45N = 133.51 - \left( \frac{3.132 \times 10^6}{HV} \right)^{1/2}$	(240–1040 HV)	$HRC = 83.58 \log HK - 179.30$	(500 gf)
$HB = 0.951 HV$	(steel ball, 200–400 HV)	$HRC = 85.848 \log HK - 184.55$	(1000 gf)
$HB = 0.941 HV$	(tungsten-carbide ball, 200–700 HV)	<b>White cast irons</b>	
		$HB = 0.363 (HRC)^2 - 22.515 (HRC) + 717.8$	
		$HV = 0.343 (HRC)^2 - 18.132 (HRC) + 595.3$	
		$HV = 1.136 (HB)^2 - 26.0$	
		<b>Austenitic stainless steel</b>	
		$\frac{1}{HB} = 0.0001304(130 - HRB)$	(60–90 HRB, 110–192 HB)
		<b>Stable alpha-beta titanium alloys</b>	
		$HRC = 0.078 HV + 8.1$	

Table 2 Approximate Rockwell B hardness conversion numbers for nonaustenitic steels

Note: Values in parentheses are beyond normal range and are given for information only. Data are for carbon and alloy steels in the annealed, normalized, and quenched-and-tempered conditions; less accurate for cold-worked condition and for austenitic steels (a) Brinell numbers are based on the diameter of impressed indentation. If the ball distorts (flattens) during test, Brinell numbers will vary in accordance with the degree of such distortion when related to hardnesses determined with a Vickers diamond pyramid, Rockwell diamond indenter, or other indenter that does not sensibly distort. At high hardnesses, therefore, the relationship between Brinell and Vickers or Rockwell scales is affected by the type of ball used. Standard steel balls tend to flatten slightly more than tungsten-carbide balls, resulting in a larger indentation and a lower Brinell number than shown by a tungsten carbide ball. Thus, on a specimen of about 539–547 HV, a standard ball will leave a 2.75 mm indentation (495 HB), and a tungsten carbide ball a 2.70 mm indentation (514 HB). Conversely, identical indentation diameters for both types of ball will correspond to different Vickers and Rockwell values. Thus, if indentation in two different specimens both are 2.75 mm diameter (495 HB), the specimen tested with a standard ball has a Vickers hardness of 539, whereas the specimen tested with a tungsten-carbide ball has a Vickers hardness of 528. Source: ASTM E 140

# Useful Formulas for Deformation Analysis and Workability Testing

**Table 1 Effective stress, strain, and strain rate (isotropic material) in arbitrary coordinates**

Variable or quantity	Symbol or equation
Stress tensor components	$\sigma_{ij}$
Strain increment components	$d\epsilon_{ij}$
Strain-rate components	$\dot{\epsilon}_{ij}$
Von Mises effective stress ( $\bar{\sigma}$ )	$\bar{\sigma} = \sqrt{\frac{1}{2} \{ (\sigma_{xx} - \sigma_{yy})^2 + (\sigma_{yy} - \sigma_{zz})^2 + (\sigma_{zz} - \sigma_{xx})^2 \} + 3\sigma_{xy}^2 + 3\sigma_{yz}^2 + 3\sigma_{zx}^2}$ <p>where <math>\sigma_{xy}</math>, <math>\sigma_{yz}</math>, and <math>\sigma_{zx}</math> are generalized tensor notation for shear stresses <math>\tau_{xy}</math>, <math>\tau_{yz}</math>, <math>\tau_{zx}</math>, respectively</p>
Von Mises effective strain increment ( $d\bar{\epsilon}$ )	$d\bar{\epsilon} = \sqrt{\frac{2}{9} \{ (d\epsilon_{xx} - d\epsilon_{yy})^2 + (d\epsilon_{yy} - d\epsilon_{zz})^2 + (d\epsilon_{zz} - d\epsilon_{xx})^2 \} + \frac{4}{3} d\epsilon_{xy}^2 + \frac{4}{3} d\epsilon_{yz}^2 + \frac{4}{3} d\epsilon_{zx}^2}$
Von Mises effective strain rate ( $\dot{\bar{\epsilon}} = d\bar{\epsilon}/dt$ )	$\dot{\bar{\epsilon}} = \sqrt{\frac{2}{9} \{ (\dot{\epsilon}_{xx} - \dot{\epsilon}_{yy})^2 + (\dot{\epsilon}_{yy} - \dot{\epsilon}_{zz})^2 + (\dot{\epsilon}_{zz} - \dot{\epsilon}_{xx})^2 \} + \frac{4}{3} \dot{\epsilon}_{xy}^2 + \frac{4}{3} \dot{\epsilon}_{yz}^2 + \frac{4}{3} \dot{\epsilon}_{zx}^2}$

**Table 2 Effective stress, strain, and strain rate (isotropic material) in principal coordinates**

Variable or quantity	Symbol or equation
Principal stress components	$\sigma_1, \sigma_2, \sigma_3$
Principal strain-increment components	$d\epsilon_1, d\epsilon_2, d\epsilon_3$
Principal strain-rate components	$\dot{\epsilon}_1, \dot{\epsilon}_2, \dot{\epsilon}_3$
Von Mises effective stress ( $\bar{\sigma}$ )	$\bar{\sigma} = \sqrt{\frac{1}{2} \{ (\sigma_1 - \sigma_2)^2 + (\sigma_2 - \sigma_3)^2 + (\sigma_3 - \sigma_1)^2 \}}$
Von Mises effective strain increment ( $d\bar{\epsilon}$ )	$d\bar{\epsilon} = \sqrt{\frac{2}{9} \{ (d\epsilon_1 - d\epsilon_2)^2 + (d\epsilon_2 - d\epsilon_3)^2 + (d\epsilon_3 - d\epsilon_1)^2 \}}$
Von Mises effective strain rate ( $\dot{\bar{\epsilon}} = d\bar{\epsilon}/dt$ )	$\dot{\bar{\epsilon}} = \sqrt{\frac{2}{9} \{ (\dot{\epsilon}_1 - \dot{\epsilon}_2)^2 + (\dot{\epsilon}_2 - \dot{\epsilon}_3)^2 + (\dot{\epsilon}_3 - \dot{\epsilon}_1)^2 \}}$

**Table 3    Formulas for compression testing of isotropic material**

Variable or quantity	Symbol or relation
<b>Uniaxial compression under uniform deformation conditions</b>	
Initial sample dimensions	Height ( $h_0$ ) Diameter ( $d_0$ ) Area ( $A_0$ ), $A_0 = \pi d_0^2/4$
Instantaneous (final) sample dimensions	Height ( $h$ ) Diameter ( $d$ ) Area ( $A$ ), $A = \pi d^2/4$
Crosshead speed	$v$
Applied load	$P$
Constant-volume assumption of plastic flow	$A_0h_0 = Ah \rightarrow d_0^2h_0 = d^2h$
Height reduction ( $R$ ), %	$R = \left[ \frac{(h_0 - h)}{h_0} \right] \times 100$
Nominal (engineering) axial strain ( $e$ ), %	$e = \left[ \frac{(h - h_0)}{h_0} \right] \times 100$
True axial strain ( $\epsilon$ )	$\epsilon = \ln \left[ \frac{h}{h_0} \right]$
True axial strain rate ( $\dot{\epsilon}$ )	$\dot{\epsilon} = -v/h$
Nominal (engineering) axial stress ( $S$ )	$S = -\frac{P}{A_0}$
True axial stress ( $\sigma$ )	$\sigma = -\frac{P}{A} = -\frac{Ph}{A_0h_0} = \frac{Sh}{h_0}$
Effective stress ( $\bar{\sigma}$ )	$\bar{\sigma} = -\sigma$
Effective strain ( $\bar{\epsilon}$ )	$\bar{\epsilon} = -\epsilon$
<b>Uniaxial compression with friction correction</b>	
Friction shear factor ( $m_s$ )	$m_s \approx \sqrt{3} \mu$ where $\mu \equiv$ Coulomb coefficient of friction
Friction correction for flow stress	$\frac{\bar{\sigma}}{p_{av}} = \left( 1 + \frac{m_s d}{(3\sqrt{3})h} \right)^{-1}$ where $\bar{\sigma}$ denotes flow stress (under homogeneous frictionless conditions) and $p_{av}$ denotes the average pressure
<b>Homogeneous plane-strain compression</b>	
Through-thickness true strain	$\epsilon_3$
Effective strain ( $\bar{\epsilon}$ )	$\bar{\epsilon} = \frac{-2\epsilon_3}{\sqrt{3}}$
True stress	$\sigma_3$
Effective stress ( $\bar{\sigma}$ )	$\bar{\sigma} = \frac{-\sigma_3\sqrt{3}}{2}$

**Table 4 Formulas for tension testing of isotropic material**

Variable or quantity	Symbol or relation
<b>Uniaxial tension under uniform deformation conditions, constant crosshead speed</b>	
Initial gage (reduced section) dimensions	Length ( $L_0$ ) Diameter ( $D_0$ ) Area ( $A_0$ ), $A_0 = \pi d_0^2/4$
Instantaneous reduced section dimensions	Length ( $L$ ) Diameter ( $d$ ) Area ( $A$ ), $A = \pi d^2/4$
Crosshead speed	$v$
Applied load	$P$
Constant-volume assumption of plastic flow	$A_0 h_0 = Ah \rightarrow d_0^2 h_0 = d^2 h$
Nominal (engineering) axial strain ( $e$ ), %	$e = \frac{(L - L_0)}{L_0} \cdot 100$
Nominal (engineering) axial strain rate ( $\dot{e}$ )	$\dot{e} = \frac{v}{L_0}$
True axial strain ( $\epsilon$ )	$\epsilon = \ln \left[ \frac{L}{L_0} \right] = \ln (1 + e)$ where $e$ is expressed as a decimal fraction
True axial strain rate ( $\dot{\epsilon}$ )	$\dot{\epsilon} = \frac{v}{L}$
Nominal (engineering) axial stress ( $S$ )	$S = \frac{P}{A_0}$
True axial stress ( $\sigma$ )	$\sigma = \frac{P}{A} = \frac{PL}{A_0 L_0} = \frac{SL}{L_0} = S(1 + e)$ where $e$ is expressed as a decimal fraction
Effective stress ( $\bar{\sigma}$ )	$\bar{\sigma} = \sigma$
Effective strain ( $\bar{\epsilon}$ )	$\bar{\epsilon} = \epsilon$
Strain-hardening exponent ( $n$ )	$n = \frac{\partial \ln \sigma}{\partial \ln \epsilon}$ evaluated at a fixed strain rate and temperature
Strain-rate sensitivity exponent ( $m$ )	$m = \frac{\partial \ln \sigma}{\partial \ln \dot{\epsilon}}$ evaluated at fixed strain and temperature
<b>Postuniform deformation in uniaxial tension of round-bar samples</b>	
Initial gage (reduced section) dimensions	Length ( $L_0$ ) Diameter ( $d_0$ ) Area ( $A_0$ ), $A_0 = \pi d_0^2/4$
Length of gage section at failure	$L_f$
Gage-section diameter at failure (minimum) section	$d_f$
Gage-section area at failure (minimum) section ( $A_f$ )	$A_f = \pi d_f^2/4$
Total elongation ( $e_t$ ), %	$e_t = \frac{(L_f - L_0)}{L_0} \cdot 100$
Reduction in area ( $RA$ ), %	$RA = \frac{(A_0 - A_f)}{A_0} \cdot 100$
True fracture strain ( $\epsilon_f$ )	$\epsilon_f = \ln \left[ \frac{A_0}{A_f} \right] = 2 \ln \left[ \frac{d_0}{d_f} \right]$
<b>Necking during tension testing of round-bar samples</b>	
Sample radius at symmetry plane of neck	$a$
Profile radius of neck	$R$
Bridgman correction for necking during tension testing of round-bar samples	$\bar{\sigma} = \frac{\sigma_x}{\left[ 1 + \frac{2R}{a} \right] \cdot \left[ \ln \left( 1 + \frac{a}{2R} \right) \right]}$ where: <ul style="list-style-type: none"> <li><math>\bar{\sigma}</math> denotes the flow stress</li> <li><math>\sigma_x</math> denotes the average axial stress (which is equal to applied load <math>\div</math> sample cross-sectional area at neck symmetry plane)</li> </ul>

**Table 5 Formulas for torsion testing of isotropic material (solid round-bar sample)**

Variable or quantity	Symbol or relation
Reduced section dimensions	Length ( $L$ ) Outer radius ( $R$ )
Radial coordinate	$r$
Twist ( $\theta$ ), in radians	$\theta$ (in radians) = twist in degrees $\times \frac{\pi}{180}$
Twist rate (in radians per second)	$\dot{\theta}$
Shear strain ( $\gamma$ )	$\gamma = \frac{r\theta}{L}$
Shear strain rate ( $\dot{\gamma}$ )	$\dot{\gamma} = \frac{r\dot{\theta}}{L}$
Effective strain ( $\bar{\epsilon}$ )	$\bar{\epsilon} = \gamma/\sqrt{3}$
Effective strain rate ( $\dot{\bar{\epsilon}}$ )	$\dot{\bar{\epsilon}} = \dot{\gamma}/\sqrt{3}$
Torque	$M$
Shear stress ( $\tau$ ) corresponding to shear strain/shear strain rate at $r = R$	$\tau = \frac{(3 + n^* + m^*) \cdot M}{2\pi R^3}$ where: $n^* = \text{slope of } \ln M \text{-vs-} \ln \theta$ $\text{plot} \approx \text{strain-hardening exponent } (n)$ $m^* = \text{slope of } \ln M \text{ vs } \ln \dot{\theta}$ $\text{plot} \approx \text{strain-rate sensitivity exponent } (m)$
Effective stress ( $\bar{\sigma}$ )	$\bar{\sigma} = \sqrt{3} \cdot \tau$

**Table 6 Formulas related to flat (sheet) rolling**

Variable or quantity	Symbol or relation
Undeformed roll radius	$R$
Rolling speed (roll surface velocity) ( $v_R$ ), m/s	$v_R = (2\pi R) \times (\text{angular velocity, in revolutions per second})$
Initial sheet thickness	$h_0$
Final sheet thickness	$h_f$
Draft ( $\Delta h$ )	$\Delta h = h_0 - h_f$
Thickness reduction, %	$\frac{(h_0 - h_f)100}{h_0}$
True thickness strain ( $\epsilon_3$ )	$\epsilon_3 = \ln \left[ \frac{h_f}{h_0} \right]$
Rolling load (roll separating force), $P_L$	$P_L = \frac{2\bar{\sigma}}{\sqrt{3}} \left[ \frac{1}{Q} (e^Q - 1) b \sqrt{R' \Delta h} \right]$ where $\bar{\sigma}$ denotes the flow stress under homogeneous uniaxial stress conditions $Q \equiv \mu L_p / \bar{h}$ $\mu \equiv$ Coulomb coefficient of friction $L_p \equiv$ projected contact length $\bar{h} \equiv (h_0 + h_f)/2$ $b \equiv$ sheet width $R' \equiv$ flattened roll radius
Hitchcock equation for flattened roll radius, $R'$	$R' = R \left\{ 1 + \frac{16(1 - \nu^2)P_L}{b\pi E(\Delta h)} \right\}$ where: $\nu \equiv$ Poisson's ratio of roll material $E \equiv$ Young's modulus of roll material
Projected contact length ( $L_p$ )	$L_p = \sqrt{R' \Delta h}$
Average effective strain rate ( $\dot{\bar{\epsilon}}$ )	$\dot{\bar{\epsilon}} = \frac{v_R}{h_0} \sqrt{\frac{2(h_0 - h_f)}{R'}}$

**Table 7    Formulas related to conical-die extrusion**

Variable or quantity	Symbol or relation
Initial billet dimensions	Diameter ( $d_0$ ) Area ( $A_0$ ), $A_0 = \pi d_0^2/4$
Final billet dimensions	Diameter $d_f$ Area ( $A_f$ ), $A_f = \pi d_f^2/4$
Die semicone angle	$\alpha$
Ram speed	$v$
Reduction ratio	$R = A_0/A_f$
Reduction ( $r$ ), %:	$r = \frac{(A_0 - A_f) \cdot 100}{A_0}$
Extrusion (ram) pressure ( $p_{av}$ )	$\frac{p_{av}}{\bar{\sigma}} = a + b \cdot \ln [R]$ where $\bar{\sigma}$ denotes material flow stress, and $a$ and $b$ denote material-dependent constants
Average effective strain rate in deformation zone ( $\dot{\bar{\epsilon}}$ )	$\dot{\bar{\epsilon}} = \frac{6vd_0^2(\tan \alpha) \ln R}{d_0^3 - d_f^3}$

**Table 8    Formulas related to wire drawing**

Variable or quantity	Symbol or relation
Initial wire diameter	$d_0$
Final wire diameter	$d_f$
Die semicone angle	$\alpha$
Reduction ratio ( $R$ )	$R = A_0/A_f$
Reduction ( $r$ ), %	$r = \frac{(A_0 - A_f)100}{A_0}$
Effective strain	$\ln \left[ \frac{A_0}{A_f} \right]$
Average drawing stress ( $\sigma_{dwg}$ )	$\frac{\sigma_{dwg}}{\bar{\sigma}} = \left( \frac{3.2}{\Delta + 0.9} \right) \cdot (\alpha + \mu)$ where: $\bar{\sigma}$ denotes material flow stress $\mu \equiv$ Coulomb coefficient of friction $\Delta$ denotes the deformation-zone geometry parameter (see below)
Deformation-zone geometry parameter ( $\Delta$ )	$\Delta \equiv \frac{\alpha}{r} \left( 1 + \sqrt{1 - r} \right)^2$ where the reduction ( $r$ ) is expressed as a decimal fraction, not as a percentage

**Table 9    Formulas related to bending**

Variable or quantity	Symbol or relation
<b>Bending of sheet</b>	
Bend radius	$R$
Sheet thickness	$h$
Minimum bend radius, $(2R/h)_{\min}$	$(2R/h)_{\min} = \frac{1}{\epsilon_f} - 1$ where $\epsilon_f$ denotes the true fracture strain in uniaxial tension.
<b>Bending of bars</b>	
Bar diameter	$d$
Mandrel diameter	$D$
Strain imposed on outer fiber	$\epsilon = \frac{1}{(1 + D/d)}$

**Table 10    Formulas related to deep drawing of cups from sheet metal**

Variable or quantity	Symbol or relation
Blank diameter	$D$
Cup diameter	$d$
Reduction ( $R$ ), %	$R = \frac{(D - d)100}{D}$
Limiting drawing ratio ( $LDR$ )	$LDR \equiv D_{\max}/d$ where $D_{\max}$ denotes the maximum blank diameter that can be drawn without cup failure

**Table 11    Formulas for anisotropic sheet materials (See also Table 12)**

Variable or quantity	Symbol or relation
<b>Basic definitions</b>	
Normal plastic anisotropy ( $R$ )	$R = d\epsilon_w/d\epsilon_t \approx \epsilon_w/\epsilon_t$ where $\epsilon_w$ , $\epsilon_t$ denote the true width and thickness strains during uniform, uniaxial tension of a sheet specimen
Average normal plastic anisotropy ( $\bar{R}$ )	$\bar{R} = (R_{0^\circ} + 2R_{45^\circ} + R_{90^\circ})/4$
Planar plastic anisotropy ( $\Delta R$ )	$\Delta R = (R_{0^\circ} - 2R_{45^\circ} + R_{90^\circ})/2$
Effective stress ( $\bar{\sigma}$ ) and effective strain increment ( $d\bar{\epsilon}$ ) assuming <i>plane-stress</i> conditions in principal coordinates and planar plastic isotropy ( $R_{0^\circ} = R_{90^\circ} = R_{45^\circ} = R$ )	$\bar{\sigma} = \sqrt{\frac{3(1+R)}{2(2+R)}} \cdot \sqrt{(\sigma_1)^2 + (\sigma_2)^2} - \frac{2R}{(1+R)}(\sigma_1\sigma_2)$ $d\bar{\epsilon} = \sqrt{\frac{2(2+R)}{3(1+2R)^2}} \cdot \sqrt{(d\epsilon_1 - Rd\epsilon_3)^2 + (d\epsilon_2 - Rd\epsilon_3)^2 + R(d\epsilon_1 - d\epsilon_2)^2}$
Hill quadratic yield function (orthotropic texture)	$F(\sigma_{yy} - \sigma_{zz})^2 + G(\sigma_{zz} - \sigma_{xx})^2 + H(\sigma_{xx} - \sigma_{yy})^2 + 2L\sigma_{yz}^2 + 2M\sigma_{zx}^2 + 2N\sigma_{xy}^2 = 1$
<b>Uniaxial sheet tension test assuming uniform deformation and planar isotropy (<math>R_{0^\circ} = R_{90^\circ} = R_{45^\circ} = R</math>)</b>	
Axial true stress	$\sigma_1$
Axial true strain	$\epsilon_1$
Effective stress ( $\bar{\sigma}$ )	$\bar{\sigma} = \sqrt{\frac{3(1+R)}{2(2+R)}} \sigma_1$
Effective strain ( $\bar{\epsilon}$ )	$\bar{\epsilon} = \sqrt{\frac{2(2+R)}{3(1+R)}} \epsilon_1$
<b>Plane-strain compression of sheet assuming uniform deformation and planar isotropy (<math>R_{0^\circ} = R_{90^\circ} = R_{45^\circ} = R</math>)</b>	
Through-thickness true stress	$\sigma_3$
Through-thickness true strain	$\epsilon_3$
Effective stress ( $\bar{\sigma}$ )	$\bar{\sigma} = -\sqrt{\frac{3(1+2R)}{2(1+R)(2+R)}} \sigma_3$
Effective strain ( $\bar{\epsilon}$ )	$\bar{\epsilon} = -\sqrt{\frac{2(2+R)(1+3R+2R^2)}{3(1+2R)^2}} \epsilon_3$
<b>Ratio of plane-strain flow stress (<math>\sigma_{ps}</math>) to uniaxial flow stress (<math>\sigma_{uni}</math>) (at equal levels of plastic work)</b>	
Ratio of plane-strain flow stress ( $\sigma_{ps}$ ) to uniaxial flow stress ( $\sigma_{uni}$ )	$\frac{\sigma_{ps}}{\sigma_{uni}} = \frac{(1+R)}{\sqrt{1+2R}}$

**Table 12** Barlat's anisotropic yield function Yld2000-2d for plane-stress deformation of sheet material (Ref 1, 2)

Variable or quantity	Symbol or relation(a)
<b>Basic definitions</b>	
Yield function ( $\phi$ ) and associated effective stress ( $\bar{\sigma}$ )	$\phi =  \tilde{S}'_1 - \tilde{S}'_2 ^a +  2\tilde{S}'_2 + \tilde{S}'_1 ^a +  2\tilde{S}'_1 + \tilde{S}'_2 ^a = 2\bar{\sigma}^a$ $(\tilde{S}'_1, \tilde{S}'_2) \text{ and } (\tilde{S}''_1, \tilde{S}''_2) \text{ are the principal values of two linearly transformed stress deviators (see below).}$ <p>Recommended values for the exponent <math>a</math> are 6 and 8 for body-centered cubic and face-centered cubic metals, respectively.</p>
Yield condition	$\bar{\sigma} = \left\{ \frac{\phi}{2} \right\}^{1/a} = h(\bar{\epsilon})$
Work-equivalent effective strain ( $\bar{\epsilon}$ ), defined incrementally for plane stress	$d\bar{\epsilon} = \frac{\alpha_x}{\bar{\sigma}} d\epsilon_{xx} + \frac{\alpha_y}{\bar{\sigma}} d\epsilon_{yy} + 2 \frac{\alpha_{xy}}{\bar{\sigma}} d\epsilon_{xy}$
Hardening function [ $h(\bar{\epsilon})$ ]	<p>Most prevalent choices:</p> <ul style="list-style-type: none"> <li>Flow stress in uniaxial tension in the rolling direction: <math>d\bar{\epsilon} = d\epsilon_{xx}</math></li> <li>Flow stress in balanced biaxial tension (<math>\sigma_{yy} = \sigma_{xx}</math>): <math>d\bar{\epsilon} = -d\epsilon_{zz}</math></li> </ul>
<b>First linear transformation</b>	
Components of the transformed stress deviator	$\tilde{S}'_{xx} = \alpha_1(2\sigma_{xx} - \sigma_{yy})/3$ $\tilde{S}'_{yy} = \alpha_2(2\sigma_{yy} - \sigma_{xx})/3$ $\tilde{S}'_{xy} = \alpha_7\sigma_{xy}$
Principal values of the transformed stress deviator	$\tilde{S}'_1 = \left\{ \tilde{S}'_{xx} + \tilde{S}'_{yy} + \sqrt{(\tilde{S}'_{xx} - \tilde{S}'_{yy})^2 + 4\tilde{S}'_{xy}{}^2} \right\} / 2$ $\tilde{S}'_2 = \left\{ \tilde{S}'_{xx} + \tilde{S}'_{yy} - \sqrt{(\tilde{S}'_{xx} - \tilde{S}'_{yy})^2 + 4\tilde{S}'_{xy}{}^2} \right\} / 2$
<b>Second linear transformation</b>	
Components of the transformed stress deviator	$\tilde{S}''_{xx} = \{ (8\alpha_5 - 2\alpha_6 - 2\alpha_3 + 2\alpha_4)\sigma_{xx} + (4\alpha_6 + \alpha_3 - 4\alpha_4 - 4\alpha_5)\sigma_{yy} \} / 9$ $\tilde{S}''_{yy} = \{ (4\alpha_3 - 4\alpha_4 - 4\alpha_5 + \alpha_6)\sigma_{xx} + (8\alpha_4 + 2\alpha_5 - 2\alpha_6 - 2\alpha_3)\sigma_{yy} \} / 9$ $\tilde{S}''_{xy} = \alpha_8\sigma_{xy}$
Principal values of the transformed stress deviator	$\tilde{S}''_1 = \left\{ \tilde{S}''_{xx} + \tilde{S}''_{yy} + \sqrt{(\tilde{S}''_{xx} - \tilde{S}''_{yy})^2 + 4\tilde{S}''_{xy}{}^2} \right\} / 2$ $\tilde{S}''_2 = \left\{ \tilde{S}''_{xx} + \tilde{S}''_{yy} - \sqrt{(\tilde{S}''_{xx} - \tilde{S}''_{yy})^2 + 4\tilde{S}''_{xy}{}^2} \right\} / 2$
<b>Coefficients and input data(b)(c)</b>	
Anisotropy coefficients	$\alpha_1$ to $\alpha_8$
Flow stresses in uniaxial tension for directions at 0, 45, and 90° from rolling direction	$\sigma_0, \sigma_{45}, \sigma_{90}$
Bulge test flow stress (assumed to be the balanced biaxial flow stress)	$\sigma_b$
$r$ values in uniaxial tension for directions at 0, 45, and 90° from rolling direction	$r_0, r_{45}, r_{90}$
Biaxial $r$ values measured with the disk compression test	$r_b = d\epsilon_{yy}/d\epsilon_{xx}$

(a) The axes ( $x, y, z$ ) denote the rolling direction, transverse direction, and normal direction of a sheet, respectively. (b) The eight anisotropy coefficients  $\alpha_1$  to  $\alpha_8$  can be calculated using a numerical solver (e.g., Newton-Raphson) using the eight physical parameters (flow stresses and  $r$  values) as input. (c) Note that  $\sigma_b$  and  $r_b$  are important experimental data to define the shape of the yield locus. However, if not available, they can be estimated using another yield function or a crystal-plasticity model.

# Glossary of Terms

---

## A

**abnormal grain growth.** Rapid, nonuniform, and usually undesirable growth of one or a small fraction of grains in a polycrystalline material during annealing. The phenomenon is most frequent in fine-grained materials in which a larger-than-average grain (or grains) consumes surrounding small grains whose growth is limited by particle pinning. Also known as *secondary recrystallization*.

**aging.** A change in material property or properties with time. See also *quench aging* and *strain aging*.

**air bend die.** Angle-forming dies in which the metal is formed without striking the bottom of the die. Metal contact is made at only three points in the cross section: the nose of the male die and the two edges of a V-shaped die opening.

**air cushion holddown.** A pneumatic pressure device used to control pressure on the blank. See also *blank holder*.

**air ejection.** The ejection of small parts away from the die by a blast of air.

**air-lift hammer.** A type of gravity-drop hammer in which the ram is raised for each stroke by an air cylinder. Because length of stroke can be controlled, ram velocity and therefore the energy delivered to the workpiece can be varied. See also *drop hammer* and *gravity hammer*.

**Almen machine.** A wear test machine in which a rotating journal is held between two stationary bushings. Load is applied by a lever arrangement.

**anelasticity.** Material characteristic where there is no specific relationship between stress and strain but rather among time, stress, and strain. In particular, anelastic strains can occur at zero stress, whereas creep strains occur as a result of imposed stress.

**angle of bite.** In the rolling of metals, the location where all of the force is transmitted through the rolls; the maximum attainable angle between the roll radius at the first contact and the line of roll centers. Operating angles less than the angle of bite are termed contact angles or rolling angles.

**angularity.** The conformity to, or deviation from, specified angular dimensions in the cross section of a shape or bar.

**anisotropy.** Variations in one or more physical or mechanical properties with direction. See also *normal anisotropy*, *planar anisotropy*, and *plastic-strain ratio*.

**annealing.** Softening or strain relieving of a material by application of heat above the critical temperature for the correct time interval, then cooling slowly enough to avoid hardening.

**anticlastic curvature.** A configuration of a sheet or beam that is curved longitudinally in one direction and transversely in the opposite direction, as the surface of a saddle. Such shapes occur naturally in bending of thin structures because of *Poisson contraction*.

**anvil.** A large, heavy metal block that supports the frame structure and holds the stationary die of a forging hammer. Also, the metal block on which blacksmith forgings are made.

**anvil cap.** Same as *sow block*.

**asperities.** Protrusions rising above the general surface contours that constitute the actual contact areas between touching surfaces.

**automatic press.** A press with built-in electrical and pneumatic control in which the work is fed mechanically through the press in synchronism with the press action.

**automatic press stop.** A machine-generated signal for stopping the action of a press, usually after a complete cycle, by disengaging the clutch mechanism and engaging the brake mechanism.

**Avrami plot.** Plot describing the kinetics of phase transformations in terms of the dependence of fraction  $X$  of microstructure that has transformed (e.g., recrystallized, decomposed, etc.) as a function of time ( $t$ ) or strain ( $\epsilon$ ). Avrami plots usually consist of a graph of  $\log [\ln(1/(1-X))]$  versus  $\log t$  (or  $\log \epsilon$ ) and are used to determine the so-called Avrami exponent  $n$  in the relation  $X = 1 - \exp(-Bt^n)$ , where  $B$  is an empirically derived parameter.

**axial rolls.** In *ring rolling*, vertically displaceable, tapered rolls mounted in a horizontally displaceable frame opposite to, but on the same centerline as, the main roll and rolling mandrel. The axial rolls control ring height during rolling.

## B

**backward extrusion.** Same as indirect extrusion. See also *extrusion*.

**bar.** (1) A section hot rolled from a *billet* to a form, such as round, hexagonal, octagonal, square, or rectangular, with sharp or rounded corners or edges and a cross-sectional area of less than 105 cm<sup>2</sup> (16 in.<sup>2</sup>). (2) A solid section that is long in relationship to its cross-sectional dimensions, having a completely symmetrical cross section and a width or greatest distance between parallel faces of 9.5 mm ( $\frac{3}{8}$  in.) or more.

**barreling.** Convexity of the surfaces of cylindrical or conical bodies, often produced unintentionally during upsetting or as a natural consequence during compression testing. See also *compression test*.

**Bauschinger effect.** A reduction in yield strength on restraining a material in the opposite direction to the initial testing. Also used more generally to denote the changes of yield stress and strain hardening following an abrupt change of strain path.

**bead.** A narrow ridge in a sheet-metal workpiece or part, commonly formed for reinforcement. See also *drawbead*.

**beaded flange.** A flange reinforced by a low ridge, used mostly around a hole.

**beading.** A forming operation in which a ridge or elongated projection is raised on sheet metal.

**beam.** A slender, flexible body with approximately equal short dimensions and one much larger dimension. When the short dimensions are greatly different, a beam becomes a sheet or a strip.

**bed.** (1) Stationary platen of a press to which the lower die assembly is attached. (2) Stationary part of the shear frame that supports the material being sheared and the fixed blade.

**bed deflection.** The deflection of the bed as a result of the rated press load. It is usually measured in inches per foot of span between supports.

**bendability.** The ability of a material to be bent around a specified radius without fracture.

**bend allowance.** The amount of sheet metal required for making a bend around a given radius. Bend allowance ( $BA$ ) is calculated by

$BA = D(0.01743R + 0.0078T)$ , where  $D$  is the number of degrees in the bend,  $R$  is the inside radius of the bend, and  $T$  is the thickness of the metal.

**bend angle.** The angle through which a bending operation is performed, that is, the supplementary angle to that formed by the two bend tangent lines or planes.

**bending.** The deformation of a part, usually a flat sheet or strip of metal, by moving it into a circular shape. See also *bending stress*.

**bending and forming.** The processes of bending, flanging, folding, twisting, offsetting, or otherwise shaping a portion of a blank or a whole blank, usually without materially changing the thickness of the metal.

**bending brake or press brake.** A form of open-frame, single-action press that is comparatively wide between the housings, with a bed designed for holding long, narrow forming edges or dies. Used for bending and forming strip, plate, and sheet (into boxes, panels, roof decks, and so on).

**bending dies.** Dies used in presses for bending sheet metal or wire parts into various shapes. The work is done by the punch pushing the stock into cavities or depressions of similar shape in the die or by auxiliary attachments operated by the descending punch.

**bending moment (or moment).** A set of balanced torques applied to a body at some distance apart in order to induce bending without overall tension or compression of the body. It is expressed in terms of force times distance and may be computed by integrating the differential force times distance from the center of the section through the section.

**bending rolls.** Various types of machinery equipped with two or more rolls to form curved sheet and sections.

**bending strain.** The tensile and compressive strains that occur throughout the thickness of a bent beam or sheet. They are usually assumed to vary linearly with distance from the neutral axis ( $Z$ ) and are equal to  $Z/R$ , where  $R$  is the radius of curvature through the neutral axis.

**bending stress.** A stress involving tensile and compressive forces, which are not uniformly distributed. Its maximum value depends on the amount of flexure that a given application can accommodate. Resistance to bending can be termed stiffness.

**bending under tension.** A forming operation in which a sheet is bent with the simultaneous application of a tensile stress perpendicular to the bend axis.

**bend (longitudinal).** A forming operation in which the axis is perpendicular to the rolling direction of the sheet.

**bend or twist (defect).** Distortion similar to warpage generally caused during forging or trimming operations. When the distortion is along the length of the part, it is termed bend; when across the width, it is termed twist. When bend or twist exceeds tolerances, it is

considered a defect. Corrective action consists of hand straightening, machine straightening, or cold restriking.

**bend radius.** The radius of a bend that corresponds to the curvature of a bent specimen or the bent area in a formed part. The radius is usually measured on the inside surface of the part but may refer to the center section or outer surface for some applications.

**bend test.** Evaluation of a sheet-metal response to a bending operation, such as around a fixed-radius tool.

**bend (transverse).** A forming operation in which the bend axis is parallel to the rolling direction of the sheet.

**biaxial stretchability.** The ability of sheet material to undergo deformation by loading in tension in two directions in the plane of the sheet.

**billet.** (1) A semifinished section that is hot rolled from a metal *ingot*, with a rectangular cross section usually ranging from 105 to 230 cm<sup>2</sup> (16 to 36 in.<sup>2</sup>), the width being less than twice the thickness. Where the cross section exceeds 230 cm<sup>2</sup> (36 in.<sup>2</sup>), the term *bloom* is properly but not universally used. Sizes smaller than 105 cm<sup>2</sup> (16 in.<sup>2</sup>) are usually termed bars. (2) A solid semifinished round or square product that has been hot worked by forging, rolling, or extrusion. See also *bar*.

**bite.** Advance of material normal to the plane of deformation and relative to the dies prior to each deformation step.

**blank.** (1) In forming, a piece of sheet material, produced in cutting dies, that is usually subjected to further press operations. (2) A piece of stock from which a forging is made; often called a *slug* or *multiple*.

**blank development.** The process of determining the optimal size and shape of a blank for a specific part.

**blank gridding.** Imprinting a metal blank with a pattern on the sheet surface, such pattern to be used for subsequent strain measurement. See also *gridding*.

**blankholder.** That part of a forming die that holds the blank by pressure against a mating surface of the die to control metal flow and prevent wrinkling. The blankholder is sometimes referred to as the holddown or binder area. Pressure is applied by mechanical means, springs, air, or fluid cushions.

**blankholder pressure.** The pressure exerted by the blankholder against the blank. This is normally adjustable to control metal flow during the drawing.

**blankholder slide.** The outer slide of a double-action press operated by toggles or cams that transfers the pressure to the blankholder.

**blanking.** The operation of punching, cutting, or shearing a piece out of stock to a predetermined shape.

**blanking die.** A die used for shearing or cutting blanks, usually from flat sheets or strip. The single blanking die used for producing one blank at each stroke of the press is the simplest

of all dies, consisting essentially of punch, die block, and stripper.

**blind die compression/pressing.** Compression in an extrusion chamber in which the die orifice has been closed off.

**blister.** A local protuberance in the surface of the sheet, often elongated, resulting from an internal separation due to the expansion of entrapped gas. The gas may be entrapped during casting, pickling, annealing, or electroplating in a previously existing subsurface defect.

**block.** A preliminary forging operation that roughly distributes metal preparatory for *finish*.

**block and finish.** The forging operation in which a part to be forged is blocked and finished in one heat through the use of tooling having both a block impression and a finish impression in the same die block.

**blocker dies.** Dies having generous contours, large radii, draft angles of 7° or more, and liberal finish allowances. See also *finish allowance*.

**blocker-type forging.** A forging that approximates the general shape of the final part with relatively generous *finish allowance* and radii. Such forgings are sometimes specified to reduce die costs where only a small number of forgings are desired and the cost of machining each part to its final shape is not excessive.

**block, first, second, and finish.** The forging operation in which a part to be forged is passed in progressive order through three tools mounted in one forging machine; only one heat is involved for all three operations.

**blocking.** A forging operation often used to impart an intermediate shape to a forging, preparatory to forging of the final shape in the finishing impression of the dies. Blocking can ensure proper working of the material and can increase die life.

**blocking impression.** The impression that gives a forging its approximate shape.

**bloom.** A semifinished hot rolled product, rectangular in cross section, produced on a blooming mill. See also *billet*. For steel, the width of a bloom is not more than twice the thickness, and the cross-sectional area is usually not less than approximately 230 cm<sup>2</sup> (36 in.<sup>2</sup>). Steel blooms are sometimes made by forging.

**blooming mill.** A primary rolling mill used to make blooms.

**board hammer.** A type of forging hammer in which the upper die and ram are attached to "boards" that are raised to the striking position by power-driven rollers and let fall by gravity. See also *drop hammer*.

**bolster.** Short for bolster plate. A heavy plate or block, sometimes called a die block, secured to the top of the bed of a press onto which a die is fastened. In some cases, the die is fastened directly to the bed and a bolster is not used.

**boss.** A relatively short, often cylindrical protrusion or projection on the surface of a forging.

**bottom draft.** Slope or taper in the bottom of a forge depression that tends to assist metal flow toward the sides of depressed areas.

**bottoming bending.** Press-brake bending process in which the upper die (punch) enters the lower die and coins or sets the material to eliminate *springback*.

**bow.** The tendency of material to curl downward during shearing, particularly when shearing long narrow strips.

**brake forming.** A forming process in which the principal mode of deformation is bending. The equipment used for this operation is commonly referred to as a press brake.

**brake press.** A form of open-frame, single-action press comparatively wide between the housings, with the bed designed for holding long narrow forming edges or dies. It is used for bending and forming strips and plates.

**brakes.** Friction brakes, set with compression springs provided on a press. Brake capacity must be sufficient to stop the motion of the slide quickly and must be capable of holding the slide and its attachments at any point in its travel.

**Bravais lattices.** The 14 possible three-dimensional arrays of atoms in crystals (see *space lattice*).

**breakdown.** (1) An initial rolling or drawing operation, or a series of such operations, for reducing an ingot or extruded shape to the desired size before the finish reduction. (2) A preliminary press-forging operation.

**brick element.** A common name for a solid, linear finite element with eight nodes.

**Bridgman correction.** Factor used to obtain the flow stress from the measured axial stress during tension testing of metals in which necking has occurred.

**brittle fracture.** A fracture that occurs without appreciable plastic deformation.

**brittleness.** A tendency to fracture without appreciable plastic deformation.

**buckling.** A bulge, bend, kink, or other wavy condition of the workpiece caused by compressive stresses. See also *compressive stress*.

**bulge test.** A test wherein the blank is clamped securely around the periphery and, by means of hydrostatic pressure, the blank is expanded. The blank is usually gridded so that the resulting strains can be measured. This test is usually performed on large blanks of 20 to 30 cm (8 to 12 in.) in diameter.

**bulging.** The process of increasing the diameter of a cylindrical shell (usually to a spherical shape) or of expanding the outer walls of any shell or box shape whose walls were previously straight.

**bulk forming.** Forming processes, such as extrusion, forging, rolling, and drawing, in which the input material is in billet, rod, or slab form and a considerable increase in surface-to-volume ratio in the formed part occurs under the action of largely compressive loading. Compare with *sheet forming*.

**bull block.** A machine with a power-driven revolving drum for cold drawing wire through

a drawing die as the wire winds around the drum.

**bulldozer.** Slow-acting horizontal *mechanical press* with a large bed used for bending and straightening. The work is done between dies and can be performed hot or cold. The machine is closely allied to a forging machine.

**Burgers vector.** The crystallographic direction along which a *dislocation* moves and the unit displacement of dislocations; the magnitude of the Burgers vector is the smallest unit distance of slip in the direction of shear due to the movement of one dislocation.

**burnishing.** The smoothing of one surface through frictional contact with another surface.

**burr.** A thin ridge or roughness left on forgings or sheet-metal blanks by cutting operations such as slitting, shearing, trimming, blanking, or sawing.

**burr side.** The side or face of a blank or other stamping that comes in direct contact with the punch in a blanking operation, and the side or face of a blank or other stamping that comes in direct contact with the die because of the clearance between punch and die.

**buster.** A pair of shaped dies used to combine preliminary forging operations, such as edging and blocking, or to loosen scale.

## C

**camber.** The tendency of material being sheared from sheet to bend away from the sheet in the same plane.

**cam press.** A mechanical press in which one or more of the slides are operated by cams; usually a double-action press in which the blankholder slide is operated by cams through which the dwell is obtained.

**canned extrusion.** A coextrusion process in which the billet consists of a clad material, or can, that is relatively ductile and nonreactive and the core is a reactive, brittle, powder, or other material.

**canning.** (1) A dished distortion in a flat or nearly flat sheet-metal surface, sometimes referred to as oil canning. (2) Distortion of a flat or nearly flat metal surface that can be deflected by finger pressure but that will return to its original position when the pressure is removed. (3) Enclosing a highly reactive metal within a relatively inert material for the purpose of hot working without undue oxidation of the reactive metal.

**capacity of a press.** The pressure, in tons, that the slide will safely exert at the bottom of the stroke in doing work within the range of the press.

**cavitation.** The formation of microscopic cavities during the cold or hot deformation of metals, generally involving a component of tensile stress. Cavities may nucleate at second-phase particles lying within grains or at grain

boundaries (with or without particles) as a result of slip intersection or grain-boundary sliding. Under severe conditions, cavities may grow and coalesce to give rise to fracture.

**cell.** Micron-sized volume bounded by low misorientation walls comprised of dislocation tangles.

**center bursting.** Internal cracking due to tensile stresses along the central axis of products being extruded or drawn.

**chamfer.** (1) A beveled surface to eliminate an otherwise sharp corner. (2) A relieved angular cutting edge at a tooth corner.

**channel forming.** A typical sheet-forming operation where a top-hat section is formed from a flat sheet by pushing a long U-shaped punch into a mating die cavity. Drawbeads are not usually used for such operations.

**check.** (1) A crack in a die impression corner, generally due to forging strains or pressure, localized at some relatively sharp corner. Die blocks too hard for the depth of the die impression have a tendency to check or develop cracks in impression corners. (2) One of a series of small cracks resulting from thermal fatigue of hot forging dies.

**chord modulus.** The slope of the chord drawn between any two specific points on a stress-strain curve. See also *modulus of elasticity*.

**chuckhead.** See *manipulator*.

**circle grid.** A regular pattern of circles, often 2.5 mm (0.1 in.) in diameter, marked on a sheet-metal blank.

**circle-grid analysis.** The analysis of deformed circles to determine the severity with which a sheet metal blank has been deformed.

**circumferential strains.** The tensile and compressive strains that arise from bending and tension of a beam or sheet; they lie in the deformed sheet plane that adopts a locally circular aspect after bending.

**clad.** Outer layer of a coextruded or codrawn product. See also *sleeve*.

**clamping pressure.** Pressure applied to a limited area of the sheet surface, usually at the periphery, to control or limit metal flow during forming.

**clearance.** (1) In punching and shearing dies, the gap between the die and the punch. (2) In forming and drawing dies, the difference between this gap and metal thickness.

**closed-die forging.** The shaping of hot metal completely within the walls or cavities of two dies that come together to enclose the workpiece on all sides. The impression for the forging can be entirely in either die or divided between the top and bottom dies. Impression-die forging, often used interchangeably with the term *closed-die forging*, refers to a closed-die operation in which the dies contain a provision for controlling the flow of excess material, or *flash*, that is generated. By contrast, in flashless forging, the material is deformed in a cavity that allows little or no escape of excess material.

**closed dies.** Forging or forming impression dies designed to restrict the flow of metal to the

cavity within the die set, as opposed to open dies, in which there is little or no restriction to lateral flow.

**closed pass.** A pass of metal through rolls where the bottom roll has a groove deeper than the bar being rolled and the top roll has a collar fitting into the groove, thus producing the desired shape free from *flash* or *fin*.

**close-tolerance forging.** A forging held to unusually close dimensional tolerances so that little or no machining is required after forging. See also *precision forging*.

**cluster mill.** A rolling mill in which each of two small-diameter work rolls is supported by two or more backup rolls.

**clutch.** The coupling mechanism used on a mechanical power press to couple the flywheel to the crankshaft, either directly or through a gear train. A full-revolution clutch is a type of clutch that, when tripped, cannot be disengaged until the crankshaft has completed a full revolution and the press side a full stroke. A part-revolution clutch is a type of clutch that can be disengaged at any point before the crankshaft has completed a full revolution and the press side a full stroke.

**coarsening.** The increase in the average size of second-phase particles, accompanied by the reduction in their number, during annealing, deformation, or high-temperature service exposure. Coarsening thus leads to a decrease in the total surface energy associated with the matrix-particle interfaces.

**codrawing.** The simultaneous drawing of two or more materials to form an integral product.

**coefficient of friction.** A measure of the ease with which one body will slide over another. It is obtained by dividing the tangential force resisting motion between the two bodies by the normal force pressing the two bodies together.

**coefficient of thermal expansion.** Defines the amount by which one unit length of a material changes (expands or contracts) when the temperature changes by one degree.

**coextrusion.** The simultaneous extrusion of two or more materials to form an integral product.

**cogging.** The reducing operation in working an ingot into a billet with a forging hammer or a forging press.

**coil breaks.** Creases or ridges that appear as parallel lines transverse to the direction of rolling and that extend across the width of the sheet. Coil breaks are caused by the deformation of local areas during coiling or uncoiling of annealed or insufficiently temper-rolled steel sheets.

**coil weld.** A welded joint connecting the ends of two coils to form a continuous strip.

**coining.** (1) A closed-die forging operation in which all surfaces of a workpiece are confined or restrained, resulting in a well-defined imprint of the die on the work. (2) A *restriking* operation used to sharpen or change an existing radius or profile. Coining can be done

while forgings are hot or cold and is usually performed on surfaces parallel to the parting line of the forging.

**coining dies.** Dies in which the coining or sizing operation is performed.

**coin straightening.** A combination coining and straightening operation performed in special cavity dies designed to impart a specific amount of working in specified areas of a forging to relieve the stresses developed during heat treatment.

**cold coined forging.** A forging that has been restruck cold in order to hold closer face distance tolerances, sharpen corners or outlines, reduce section thickness, flatten some particular surface, or, in non-heat-treatable alloys, increase hardness.

**cold forming.** See *cold working*.

**cold heading.** Working metal at room temperature such that the cross-sectional area of a portion or all of the stock is increased. See also *heading* and *upsetting*.

**cold lap.** A flaw that results when a workpiece fails to fill the die cavity during the first forging. A seam is formed as subsequent dies force metal over this gap to leave a seam on the workpiece surface. See also *cold shut*.

**cold rolled sheet.** A mill product produced from a hot rolled pickled coil that has been given substantial cold reduction at room temperature. After annealing, the usual end product is characterized by improved surface, greater uniformity in thickness, increased tensile strength, and improved mechanical properties as compared with hot rolled sheet.

**cold shut.** (1) A fissure or lap on a forging surface that has been closed without fusion during the forging operation. (2) A folding back of metal onto its own surface during flow in the die cavity; a forging defect.

**cold trimming.** The removal of flash or excess metal from a forging at room temperature in a trimming press.

**cold working.** The plastic deformation of metal under conditions of temperature and strain rate that induce *strain hardening*. Usually, but not necessarily, conducted at room temperature. Also referred to as cold forming or cold forging. Contrast with *hot working*.

**combination die.** See *compound die*.

**compact** (noun). The object produced by the compression of metal powder, generally while confined in a die.

**compact** (verb). The operation or process of producing a compact; sometimes called pressing.

**compound die.** Any die designed to perform more than one operation on a part with one stroke of the press, such as blanking and piercing, in which all functions are performed sequentially within the confines of the blank size being worked.

**compression test.** A method for assessing the ability of a material to withstand compressive loads.

**compressive strength.** The maximum compressive stress a material is capable of devel-

oping. With a brittle material that fails in compression by fracturing, the compressive strength has a definite value. In the case of ductile, malleable, or semiviscous materials (which do not fail in compression by a shattering fracture), the value obtained for compressive strength is an arbitrary value dependent on the degree of distortion that is regarded as effective failure of the material.

**compressive stress.** A stress that causes an elastic or plastic body to deform (shorten) in the direction of the applied load.

**connections.** Connecting members that convey motion and force from a rotating member to a slide or lever on a press. Also called pitmans, connecting links (or rods and straps), or eccentric straps.

**constitutive equation.** Equation expressing the relation between stress, strain, strain rate, and microstructural features (e.g., grain size). Constitutive equations are generally phenomenological (curve fits based on measured data) or mechanism-based (based on mechanistic model of deformation and appropriate measurements). Phenomenological constitutive equations are usually valid only within the processing regime in which they were measured, while mechanism-based relations can be extrapolated outside the regime of measurement, provided the deformation mechanism is unchanged.

**contour forming.** See *roll forming*, *stretch forming*, *tangent bending*, and *wiper forming*.

**controlled rolling.** Multistand plate or bar rolling process, typically for ferrous alloys, in which the reduction per pass, rolling speed, time between passes, and so on are carefully chosen to control recrystallization, precipitation, and phase transformation in order to develop a desired microstructure and set of properties.

**controller.** A control algorithm implemented in a closed-loop control system.

**conventional forging.** Forging process in which the work material is hot and the dies are at room temperature or slightly elevated temperature. To minimize the effects of die chilling on metal flow and microstructure, conventional forging usually involves strain rates of the order of  $0.05 \text{ s}^{-1}$  or greater. Also known as nonisothermal forging.

**core.** Inner material in a coextruded or codrawn product.

**core rod.** See *mandrel*.

**coring.** (1) A central cavity at the butt end of a rod extrusion; sometimes called *extrusion pipe*. (2) A condition of variable composition between the center and surface of a unit of microstructure (such as a dendrite, grain, or carbide particle); results from nonequilibrium solidification, which occurs over a range of temperature.

**corrugating.** The forming of sheet metal into a series of straight, parallel alternate ridges and grooves with a rolling mill equipped with matched roller dies or a *press brake* equipped with specially shaped punch and die.

**corrugations.** Transverse ripples caused by a variation in strip shape during hot or cold reduction.

**Coulomb friction.** Interface friction condition for which the interface shear stress is proportional to the pressure normal to the interface. The proportionality constant is called the Coulomb coefficient of friction ( $\mu$ ) and takes on values between 0 (perfect lubrication) and  $1/\sqrt{3}$  (sticking friction) during metalworking. See also *friction shear factor*.

**counterblow equipment.** Equipment with two opposed rams that are activated simultaneously to strike repeated blows on the workpiece placed midway between them.

**counterblow forging equipment.** A category of forging equipment in which two opposed rams are activated simultaneously, striking repeated blows on the workpiece at a midway point. Action is vertical or horizontal.

**counterblow hammer.** A forging hammer in which both the ram and the anvil are driven simultaneously toward each other by air or steam pistons.

**counterlock.** A jog in the mating surfaces of dies to prevent lateral die shift caused by side thrust during the forging of irregularly shaped pieces.

**cracked edge.** A series of tears at the edge of the sheet resulting from prior processing.

**crank.** Forging shape generally in the form of a "U" with projections at more or less right angles to the upper terminals. Crank shapes are designated by the number of throws (for example, two-throw crank).

**crank press.** A mechanical press whose slides are actuated by a crankshaft.

**creep.** Time-dependent strain occurring under stress.

**creep forming.** Forming, usually at elevated temperatures, where the material is deformed over time with a preload, sometimes comprising weights placed on a part during a stress-relief cycle.

**crimping.** The forming of relatively small *corrugations* in order to set down and lock a seam, to create an arc in a strip of metal, or to reduce an existing arc or diameter. See also *corrugating*.

**cross breaks.** Visually apparent line-type discontinuities more or less transverse to the coil rolling direction resulting from bending the coil over too sharp a radius and thus kinking the metal.

**crown.** (1) The upper part (head) of a press frame. On hydraulic presses, the crown usually contains the cylinder; on mechanical presses, the crown contains the drive mechanism. See also *hydraulic press* and *mechanical press*. (2) A shape (crown) ground into a flat roll to ensure uniform gage control and coil tracking during rolling of cold (and hot) rolled sheet and strip.

**crystal.** A solid composed of atoms, ions, or molecules arranged in a pattern that is periodic in three dimensions.

**crystal lattice.** A regular array of points about which the atoms or ions of a crystal are centered. See also *lattice*.

**crystal-plasticity modeling.** Physics-based modeling techniques that treat the phenomena of deformation by way of slip and twinning in order to predict strength and the evolution of crystallographic texture during the deformation processing of polycrystalline materials. See also *deformation texture*, *slip*, *Schmid's law*, *Taylor factor*, and *twinning*.

**crystal system.** One of seven groups into which all crystals may be divided: triclinic, monoclinic, orthorhombic, hexagonal, rhombohedral, tetragonal, and cubic.

**cup.** (1) A sheet-metal part; the product of the first drawing operation. (2) Any cylindrical part or shell closed at one end.

**cup fracture (cup-and-cone fracture).** A mixed-mode fracture, often seen in tensile test specimens of a ductile material, in which the central portion undergoes plane-strain fracture and the surrounding region undergoes plane-stress fracture. One of the mating fracture surfaces looks like a miniature cup; it has a central depressed flat-face region surrounded by a shear lip. The other fracture surface looks like a miniature truncated cone.

**cupping.** (1) The first step in *deep drawing*. (2) Fracture of severely worked rods or wire in which one end looks like a cup and the other a cone.

**cupping test.** A mechanical test used to determine the ductility and stretching properties of sheet metal. It consists of measuring the maximum part depth that can be formed before fracture. The test is typically carried out by stretching the testpiece clamped at its edges into a circular die using a punch with a hemispherical end. See also *cup fracture*, *Erichsen test*, and *Olsen ductility test*.

**curling.** Forming of an edge of circular cross section along a sheet or along the end of a shell or tube, either to the inside or outside, for example, the pinholes in sheet-metal hinges and the curled edges on cans, pots, and pans.

**curling die.** (1) A die used when the curling is done in the die block (female part), such as curling of sheet-metal hinges and the edge plate preparatory to seaming. (2) A die that is ordinarily attached to the punch holder, such as those used in wiring of pots and pans.

**curvature.** The reciprocal of the radius of curvature; it expresses how curved a body is.

**cushion.** A mechanism mounted in or under the bed of a hydraulic press to provide a controlled resistance against the work as it is displaced by the slide. The return motion may also be used for ejecting the work.

**cushion, hydraulic.** A *cushion* in which a hydraulic cylinder provides the resistance. Pressure in the cylinder is developed by the main ram movement. The cushion is returned to its normal position by gas pressure acting on the hydraulic fluid in the reservoir.

**cushion, hydropneumatic.** A *cushion* in which a hydraulic cylinder provides the resistance.

Pressure in the cylinder is developed by the main ram movement. The cushion is returned to its normal position by gas pressure acting on the hydraulic fluid in the reservoir.

**cutoff.** A pair of blades positioned in dies or equipment (or a section of the die milled to produce the same effect as inserted blades) used to separate a forging from a bar after forging operations are completed. Used only when forgings are produced from relatively long bars instead of from individual, precut multiples or blanks. See also *blank* and *multiple*.

**cut-off die.** (1) The last die in a set of transfer dies that cuts the part loose from the scrap. Also known as a trimming die. (2) A die that cuts straight-sided blanks from a coil for later use in a draw die.

## D

**damage.** General term used to describe the development of defects such as cavities, cracks, shear bands, and so on that may culminate in gross fracture in severe cases. The evolution of damage is strongly dependent on material, microstructure, and processing conditions (strain, strain rate, temperature, and stress state).

**daylight.** The maximum clear distance between the pressing surfaces of a press when the surfaces are in the usable open position. Where a *bolster* plate is supplied, it is considered the pressing surface. See also *shut height*.

**DBTT.** See *ductile-to-brittle transition temperature (DBTT)*.

**dead-metal zone.** Region of metal undergoing limited or no deformation during bulk forming of a workpiece, generally developed adjacent to the workpiece-tooling interface as a result of friction, die chilling, or deformation-zone geometry.

**deep drawing.** Forming operation characterized by the production of a parallel-wall cup from a flat blank of sheet metal. The blank may be circular, rectangular, or a more complex shape. The blank is drawn into the die cavity by the action of a punch. Deformation is restricted to the flange areas of the blank. No deformation occurs under the bottom of the punch—the area of the blank that was originally within the die opening. As the punch forms the cup, the amount of material in the flange decreases. Also called *cup drawing* or *radial drawing*.

**deflection.** The amount of deviation from a straight line or plane when a force is applied to a press member. Generally used to specify the allowable bending of the bed, slide, or frame at rated capacity with a load of predetermined distribution.

**deformation (adiabatic) heating.** Temperature increase that occurs in a workpiece due to the conversion of strain energy, imparted during metalworking, into heat.

**deformation energy method.** A metal-forming analysis technique that takes into account only the energy required to deform the workpiece.

**deformation limit.** In *drawing*, the limit of deformation is reached when the load required to deform the flange becomes greater than the load-carrying capacity of the cup wall. The deformation limit (limiting drawing ratio, LDR) is defined as the ratio of the maximum blank diameter that can be drawn into a cup without failure, to the diameter of the punch.

**deformation-mechanism map.** Strain rate/temperature map that describes forming or service regimes under which deformation is controlled by micromechanical processes such as dislocation glide, dislocation climb, and diffusional flow limited by bulk or boundary diffusion.

**deformation texture.** Preferred orientation of the crystals/grains comprising a polycrystalline aggregate that is developed during deformation processing as a result of slip and rotation within each crystal that comprises the aggregate.

**degree of freedom.** A single scalar variable that may vary at a node and for which a solution is sought. For example, if a node was allowed to move in three-dimensional space, it would have three degrees of freedom. If, in addition, the temperature was unknown and to be determined, there would be four degrees of freedom at each node.

**delayed return.** A controlling device for a *cushion* to prevent its return until the main ram has returned a predetermined distance.

**Demarest process.** A *fluid forming* process in which cylindrical and conical sheet-metal parts are formed by a modified rubber bulging punch. The punch, equipped with a hydraulic cell, is placed inside the workpiece, which in turn is placed inside the die. Hydraulic pressure expands the punch.

**density.** Mass per unit volume. Weight per unit volume.

**design of experiments.** Methodology for choosing a small number of screening experiments to establish the important material and process variables in a complex manufacturing process.

**developed blank.** A sheet-metal blank that yields a finished part without trimming or with the least amount of trimming.

**die.** (1) A tool, usually containing a cavity, that imparts shape to solid, molten, or powdered metal primarily because of the shape of the tool itself. Used in many press operations (including blanking, drawing, forging, and forming), in die casting, and in forming green powder metallurgy compacts. Die-casting and powder metallurgy dies are sometimes referred to as molds. See also *forging dies*. (2) A complete tool used in a press for any operation or series of operations, such as forming, impressing, piercing, and cutting. The upper member or members are attached to the slide (or slides) of the press, and the lower member is clamped or bolted to the bed or

bolster, with the die members being so shaped as to cut or form the material placed between them when the press makes a stroke. (3) The female part of a complete die assembly as described previously.

**die assembly.** The parts of a die stamp or press that hold the die and locate it for the punches.

**die block.** A block, often made of heat treated steel, into which desired impressions are machined or sunk and from which closed-die forgings or sheet-metal stampings are produced using hammers or presses. In forging, die blocks are usually used in pairs, with part of the impression in one of the blocks and the rest of the impression in the other. In sheet-metal forming, the female die is used in conjunction with a male punch. See also *closed-die forging*.

**die button.** An insert in a die that matches the punch and is used for punching and piercing operations. The die button is readily removable for sharpening or replacement as an individual part of a die.

**die cavity.** The machined recess that gives a forging or stamping its shape.

**die check.** A crack in a die impression due to forging and thermal strains at relatively sharp corners. Upon forging, these cracks become filled with metal, producing sharp, ragged edges on the part. Usual die wear is the gradual enlarging of the die impression due to erosion of the die material, generally occurring in areas subject to repeated high pressures during forging.

**die chill.** The temperature loss experienced by a billet or preform when it contacts dies that are maintained at a lower temperature.

**die clearance.** Clearance between a mated punch and die; commonly expressed as clearance per side. Also called clearance or punch-to-die clearance.

**die closure.** A term frequently used to mean variations in the thickness of a forging.

**die coating.** Hard metal incorporated into the working surface of a die to protect the working surface or to separate the sheet-metal surface from direct contact with the basic die material. Hard-chromium plating is an example.

**die cushion.** A press accessory placed beneath or within a *bolster* plate or *die block* to provide an additional motion or pressure for stamping or forging operations; actuated by air, oil, rubber, springs, or a combination of these.

**die forging.** A forging that is formed to the required shape and size through working in machined impressions in specially prepared dies.

**die forming.** The shaping of solid or powdered metal by forcing it into or through the *die cavity*.

**die height.** The distance between the fixed and the moving platen when the dies are closed.

**die holder.** A plate or block, on which the die block is mounted, having holes or slots for fastening to the *bolster* plate or the *bed* of the press.

**die impression.** The portion of the die surface that shapes a forging or sheet-metal part.

**die insert.** A relatively small die that contains part or all of the impression of a forging or sheet-metal part and is fastened to the master *die block*.

**die life.** The productive life of a *die impression*, usually expressed as the number of units produced before the impression has worn beyond permitted tolerances.

**die line.** A line or scratch resulting from the use of a roughened tool or the drag of a foreign particle between tool and product.

**die lock.** A phenomenon in which the deformation is limited in a forging near the die face due to chilling of the workpiece and/or friction at the workpiece-die interface.

**die lubricant.** In forging or forming, a compound that is sprayed, swabbed, or otherwise applied on die surfaces or the workpiece during the forging or forming process to reduce friction. Lubricants also facilitate release of the part from the dies and provide thermal insulation. See also *lubricant*.

**die match.** The alignment of the upper (moving) and lower (stationary) dies in a hammer or press. An allowance for misalignment (or mismatch) is included in forging tolerances.

**die pad.** A movable plate or pad in a female die; usually used for part ejection by mechanical means, springs, or fluid cushions.

**die proof (cast).** A casting of a *die impression* made to confirm the accuracy of the impression.

**die radius.** The radius on the exposed edge of a deep-drawing die, over which the sheet flows in forming drawn shells.

**die section.** A section of a cutting, forming, or flanging die that is fastened to other sections to make up the complete working surface. Also referred to as cutting section.

**die set.** (1) The assembly of the upper and lower die shoes (punch and die holders), usually including the *guide pins*, *guide pin bushings*, and *heel blocks*. This assembly takes many forms, shapes, and sizes and is frequently purchased as a commercially available unit. (2) Two (or, for a mechanical upsetter, three) machined dies used together during the production of a *die forging*.

**die shift.** The condition that occurs after the dies have been set up in a forging unit in which a portion of the impression of one die is not in perfect alignment with the corresponding portion of the other die. This results in a mismatch in the forging, a condition that must be held within the specified tolerance.

**die shoes.** The upper and lower plates or castings that constitute a *die set* (punch and die holder). Also a plate or block on which a *die holder* is mounted, functioning primarily as a base for the complete *die assembly*. This plate or block is bolted or clamped to the *bolster* plate or the face of the press *slide*.

**die sinking.** The machining of the die impressions to produce forgings of required shapes and dimensions.

**die space.** The maximum space (volume), or any part of the maximum space, within a press for mounting a die.

**die stamping.** The general term for a sheet-metal part that is formed, shaped, or cut by a die in a press in one or more operations.

**dimpling.** (1) The stretching of a relatively small, shallow indentation into sheet metal. (2) In aircraft, the stretching of metal into a conical flange for a countersunk head rivet.

**direct (forward) extrusion.** See *extrusion*.

**discontinuous yielding.** The nonuniform plastic flow of a metal exhibiting a yield point in which plastic deformation is inhomogeneously distributed along the gage length. Under some circumstances, it may occur in metals not exhibiting a distinct yield point, either at the onset of or during plastic flow.

**dishing.** The formation of a shallow concave surface in which the projected area is very large compared with the depth of the impression.

**dislocation.** Line imperfection in an otherwise perfect crystal. Allows deformation of metals at much lower forces than would be required for perfect crystals. The two basic types are an *edge dislocation* and a *screw dislocation*.

**displacement adjustment (DA) method.** A *springback* compensation method characterized by a step in which the die shape is adjusted by applying error displacements computed in a springback calculation, with the objective of attaining a die shape that will produce a desired shape after springback.

**double-action hydraulic press.** Press equipped with two moving slide members, both located on the same side of the work. Three designs are in general use:

1. **Slide within a slide.** The outer, or blankholder, slide is guided on housings or strain rods. The inner, or punch, slide is guided in the outer slide.
2. **Slide below a slide.** The lower slide is the blankholder slide. It is provided with a center hold to allow the punch to come through. Both slides are guided on housings or strain rods.
3. **Blankholder above punch slide.** Both slides are guided on housings or straight rods. Pins connect the blankholder ring (which is below the main, or punch, slide) to the blankholder slide above the main slide.

A double-action press may have a *cushion* built into the bed.

**double-action mechanical press.** A press having two independent parallel movements by means of two slides, one moving within the other. The inner slide or plunger is usually operated by a crankshaft; the outer or blankholder slide, which dwells during the drawing operation, is usually operated by a toggle mechanism or by cams. See also *slide*.

**double-action press.** A press with two mechanically or hydraulically actuated

slides: an inner or forming slide and an outer blankholder slide.

**double-bend die.** A punch and die combination that makes two bends in one motion.

**double-cone test.** Simulative bulk forming test consisting of the compression of a sample shaped like a flying saucer between flat dies. The variation of strain and stress state developed across the sample is used to obtain a large quantity of data on microstructure evolution and failure in a single experiment.

**double-crank press.** A crank press in which the slide is driven by two connections.

**double-drive eccentric.** An eccentric gear drive consisting of an eccentric between two gears. It is generally made of one-piece construction and rotates on a stationary shaft.

**DQSK steel.** Drawing-quality, special-killed steel; a typical low-strength steel used for sheet-forming applications in the automotive industry.

**draft.** The amount of taper on the sides of a forging and on projections to facilitate removal from the dies; also, the corresponding taper on the sidewalls of the die impressions. In *open-die forging*, draft is the amount of relative movement of the dies toward each other through the metal in one application of power. See also *draft angle*.

**draft angle.** The angle of taper, usually 5 to 7°, given to the sides of a forging and the sidewalls of the die impression. See also *draft*.

**drawability.** A measure of the *formability* of a sheet-metal subject to a drawing process. The term is usually used to indicate the ability of a metal to be deep drawn. See also *drawing* and *deep drawing*.

**drawbead.** Narrow ridges along the edge of a part, and corresponding ridges in the die, to improve holding action in pressworking. The insert or riblike projection on the draw ring or holddown surfaces aids in controlling the rate of metal flow during deep-drawing operations. Drawbeads are especially useful in controlling the rate of metal flow in irregularly shaped stampings.

**draw-bend.** A deformation state for a sheet that is pulled over a radius such that at each location along the length the sheet undergoes bending with tension and then unbending with tension. It corresponds to sheet that is drawn into a die cavity in typical sheet-metal forming operations. Also called *stretch-bend*.

**draw forming.** A method of curving bars, tubes, or rolled or extruded sections in which the stock is bent around a rotating *form block*. Stock is bent by clamping it to the form block, then rotating the form block while the stock is pressed between the form block and a pressure die held against the periphery of the form block.

**draw-in constraints.** Any impediment to the draw-in of sheet into a die cavity, by, for example, drawbeads, binder friction, and so on.

**drawing.** A term used for a variety of forming operations, such as *deep drawing* a sheet-

metal blank; *redrawing* a tubular part; and drawing rod, wire, and tube. The usual drawing process with regard to sheet-metal working in a press is a method for producing a cuplike form from a sheet-metal disk by holding it firmly between blankholding surfaces to prevent the formation of wrinkles while the punch travel produces the required shape.

**drawing compound.** A substance applied to prevent *pickup* and scoring during deep drawing or pressing operations by preventing metal-to-metal contact of the workpiece and die. Also known as *die lubricant*.

**drawing die.** A type of die designed to produce nonflat parts such as boxes, pans, and so on. Whenever practical, the die should be designed and built to finish the part in one stroke of the press, but if the part is deep in proportion to its diameter, redrawing operations are necessary.

**drawing ratio.** The ratio of the blank diameter to the punch diameter.

**draw marks.** See *scoring*, *galling*, *pickup*, and *die line*.

**draw plate.** A circular plate with a hole in the center contoured to fit a forming punch; used to support the *blank* during the forming cycle.

**draw radius.** The radius at the edge of a die or punch over which sheet metal is drawn.

**draw ring.** A ring-shaped die part (either the die ring itself or a separate ring) over which the inner edge of sheet metal is drawn by the punch.

**draw stock.** The forging operation in which the length of a metal mass (stock) is increased at the expense of its cross section; no *upset* is involved. The operation includes converting ingot to pressed bar using "V," round, or flat dies.

**drop forging.** The forging obtained by hammering metal in a pair of closed dies to produce the form in the finishing impression under a *drop hammer*; forging method requiring special dies for each shape.

**drop hammer.** A term generally applied to forging hammers in which energy for forging is provided by gravity, steam, or compressed air. See also *air-lift hammer*, *board hammer*, and *steam hammer*.

**drop hammer forming.** A process for producing shapes by the progressive deformation of sheet metal in matched dies under the repetitive blows of a gravity-drop or power-drop hammer. The process is restricted to relatively shallow parts and thin sheet from approximately 0.6 to 1.6 mm (0.024 to 0.064 in.).

**drop through.** The type of ejection where the part or scrap drops through an opening in the die.

**dry-film lubricant.** A type of lubricant applied by spraying or painting on coils or sheets prior to blanking, drawing, or stamping. The lubricant can have a wax base and be sprayed hot onto the sheet surface and solidify on cooling, or be a water-based polymer and be roll coated onto the surface (one or both sides) and be

heated to cure and dry. Such lubricants have uniform thickness, low coefficients of friction, and offer protection from corrosion in transit and storage.

**ductile fracture.** Failure of metals as a result of cavity nucleation, growth, and coalescence. Ductile fracture may occur during metal forming at both cold and hot working temperatures.

**ductile-to-brittle transition temperature (DBTT).** A temperature or range of temperatures over which a material reaction to impact (high strain rate) loads changes from ductile, high-energy-absorbing to brittle, low-energy-absorbing behavior. The DBTT determinations are often done with Charpy or Izod test specimens measuring absorbed energy at various temperatures.

**ductility.** A measure of the amount of deformation that a material can withstand without breaking.

**dummy block.** In *extrusion*, a thick, unattached disk placed between the ram and the billet to prevent overheating of the ram.

**dynamic friction.** The friction forces between two surfaces in relative motion. See also *static friction*.

**dynamic material modeling.** A methodology by which macroscopic measurements of flow stress as a function of temperature and strain rate are used with continuum criteria of instability to identify regions of temperature and strain rate in which voids, cracks, shear bands, and flow localization are likely to occur.

**dynamic recovery.** Recovery process that occurs during cold or hot working of metals, typically resulting in the formation of low-energy dislocation substructures/subgrains within the deformed original grains. Dynamic recovery reduces the observed level of strain hardening due to dislocation multiplication during deformation.

**dynamic recrystallization.** The formation of strain-free recrystallized grains during hot working. It results in a decrease in flow stress and formation of equiaxed grains, as opposed to dynamic recovery in which the elongated grains remain.

**dwell.** Portion of a press cycle during which the movement of a member is zero or at least insignificant. Usually refers to (1) the interval when the *blankholder* in a drawing operation is holding the blank while the punch is making the draw, or (2) the interval between the completion of the forging stroke and the retraction of the ram.

## E

**earring.** The formation of ears or scalloped edges around the top of a drawn shell, resulting from directional differences in the plastic-working properties of rolled metal with, across, and at angles to the direction of rolling.

**eccentric.** The offset portion of the driveshaft that governs the stroke or distance the cross-head moves on a mechanical or manual shear.

**eccentric gear.** A main press-drive gear with an eccentric(s) as an integral part. The unit rotates about a common shaft, with the eccentric transmitting the rotary motion of the gear into the vertical motion of the slide through a connection.

**eccentric gear press.** A press where the rotary motion is converted to reciprocating motion by means of an eccentric journal integral with a drive gear and rotating on a stationary shaft. Eccentric gear drives are commonly used in presses of over 300 tons capacity.

**eccentric press.** A *mechanical press* in which an eccentric, instead of a crankshaft, is used to move the *slide*.

**eccentric shaft press.** A press where the rotary motion is converted to reciprocating motion by means of an eccentric shaft. The eccentric is a crank with a pin of such size that its diameter contains or surrounds the shaft diameter.

**edge dislocation.** A line imperfection that corresponds to the row of mismatched atoms along the edge formed by an extra, partial plane of atoms within the body of a crystal.

**edger (edging impression).** The portion of a die impression that distributes metal during forging into areas where it is most needed in order to facilitate filling the cavities of subsequent impressions to be used in the forging sequence. See also *fuller (fullering impression)*.

**edge strain.** Repetitive areas of local deformation extending inwardly from the edge of temper-rolled sheet.

**edging.** (1) In sheet-metal forming, reducing the flange radius by retracting the forming punch a small amount after the stroke but before release of the pressure. (2) In rolling, the working of metal in which the axis of the roll is parallel to the thickness dimension. Also called edge rolling. The result is changing a rounded edge to a square edge. (3) The forging operation of working a bar between contoured dies while turning it 90° between blows to produce a varying rectangular cross section.

**effective draw.** The maximum limits of forming depth that can be achieved with a multiple-action press; sometimes called maximum draw or maximum depth of draw.

**effective strain.** A scalar measure of strain for a general strain state that is equivalent to a tensile strain corresponding to the same material hardness. Effective strains can be similarly defined for other yield functions but are seldom used without clarification. Effective strain is a scalar conjugate to effective stress, defined in such a manner that the product of the effective stress and the effective strain increment is equal to the increment in imposed work during a deformation process. Also known as von Mises strain.

**effective stress.** A scalar measure of stress for a general stress state that is equivalent to a

tensile stress corresponding to the same material state. Effective stresses can be similarly defined for other yield functions but are seldom used without clarification. Effective stress is a mathematical way to express a two- or three-dimensional stress state by a single number. Also known as von Mises stress.

**ejection.** (1) Gravity: the ejection of parts by the force of gravity. (2) Kicker: the ejection of parts by means of a mechanical device that pushes the part away from the die.

**ejector.** A mechanism for removing work or material from between the dies.

**ejector rod.** A rod used to push out a formed piece.

**elastic core.** The region near the neutral axis in a bent beam where the stresses are less than the yield stress, such that the material behaves elastically.

**elastic deformation.** Deformation that is reversed upon removal of the forces that created the deformation. Theoretically, no net work should be done during a closed path of elastic deformation.

**elasticity.** The property of a material that permits elastic deformation to occur.

**elastic limit.** The maximum stress a material can sustain without permanent strain remaining upon complete release of the stress. See also *proportional limit*.

**elastic modulus.** See *Young's modulus*.

**elastic-plastic or elastoplastic.** An adjective describing a material or constitutive equation that incorporates both elastic and plastic material properties, depending on the stress state, its magnitude, and their increments.

**elastohydrodynamic lubrication.** A condition of lubrication in which the friction and film thickness between two bodies in relative motion is determined by the elastic properties of the bodies in combination with the viscous properties of the lubricant. See also *thin-film lubrication*.

**electric-discharge machining (EDM).** Metal removal (machining) process based on the electric discharge/spark erosion resulting from current flowing between an electrode and workpiece placed in close proximity to each other in a dielectric fluid. The electrode may be a wire (as in wire EDM) or a contoured shape (so-called plunge EDM); the latter technique is used for making metalworking dies.

**electromagnetic forming.** A process for forming metal by the direct application of an intense, transient magnetic field. The workpiece is formed without mechanical contact by the passage of a pulse of electric current through a forming coil. Also known as magnetic pulse forming.

**electron backscatter diffraction (EBSD).** Materials characterization technique conducted in a scanning electron microscope (and sometimes a transmission electron microscope) used to establish the crystallographic orientation of individual (micron-sized) regions of material through analysis of

Kikuchi patterns formed by backscattered electrons. Automated EBSD systems can thus be used to determine the texture over small-to-moderate-sized total volumes of material.

**elongation.** A term used in mechanical testing to describe the amount of extension of a testpiece when deformed. See also *elongation, percent*.

**elongation, percent.** The extension of a uniform section of a specimen expressed as a percentage of the original gage length:

$$\text{Elongation, \%} = \frac{(L_x - L_o)}{L_o} \times 100$$

where  $L_o$  is the original gage length, and  $L_x$  is the final gage length.

**embossing.** A process for producing raised or sunken designs in sheet material by means of male and female dies, theoretically with minimal change in metal thickness. Examples are letters, ornamental pictures, and ribs for stiffening. Heavy embossing and *coining* are similar operations.

**embossing die.** A die used for producing embossed designs.

**engineering strain.** A measure of the strain proportional to extension in one direction that is obtained from:  $e = (l - l_o)/l_o$ , where  $l$  is the final length, and  $l_o$  is the original length in the direction of interest. Preferred term is *nominal strain*.

**engineering stress.** A measure of stress proportional to external load in one direction that is obtained by dividing the differential normal load carried by a cross section by the original (before deformation) differential area corresponding to that differential load. Preferred term is *nominal stress*.

**equal channel angular extrusion (ECAE).** Metalworking operation comprising the extrusion of a billet through two intersecting channels of identical cross section lying at a specified angle to each other, thus imparting large deformation in a single pass or multiple passes. Also sometimes referred to as equal channel angular pressing (ECAP).

**Erichsen test.** A *cupping test* used to assess the ductility of sheet metal. The method consists of forcing a conical or hemispherical-ended plunger into the specimen and measuring the depth of the impression at fracture.

**erosion resistance.** The ability of a die material to resist sliding wear and thus maintain its original dimension.

**etching.** Production of designs, including grids, on a metal surface by a corrosive reagent or electrolytic action.

**Euler angles.** Set of three angular rotations used to specify unambiguously the spatial orientation of crystallites relative to a fixed reference frame.

**explicit.** A type of finite element algorithm where an incremental solution for a very small step is assumed based on current conditions. No iteration is required. A solution is ensured, but the accuracy cannot be. Typical sheet-forming programs of this type are based on

momentum effects and are thus often called dynamic explicit programs.

**explosive forming.** The shaping of metal parts in which the forming pressure is generated by an explosive charge. See also *high-energy-rate forming*.

**extruded hole.** A hole formed by a punch that first cleanly cuts a hole and then is pushed farther through to form a flange with an enlargement of the original hole. This may be a two-step operation.

**extrusion.** The conversion of an ingot or billet into lengths of uniform cross section by forcing metal to flow plastically through a die orifice. In forward (direct) extrusion, the die and ram are at opposite ends of the extrusion stock, and the product and ram travel in the same direction. Also, there is relative motion between the extrusion stock and the die. In backward (indirect) extrusion, the die is at the ram end of the stock, and the product travels in the direction opposite that of the ram, either around the ram (as in the impact extrusion of cylinders, such as cases for dry cell batteries) or up through the center of a hollow ram. See also *hydrostatic extrusion* and *impact extrusion*.

**extrusion billet.** A metal slug used as *extrusion stock*.

**extrusion defect.** See *extrusion pipe*.

**extrusion forging.** (1) Forcing metal into or through a die opening by restricting flow in other directions. (2) A part made by the operation.

**extrusion pipe.** A central oxide-lined discontinuity that occasionally occurs in the last 10 to 20% of an extruded bar. It is caused by the oxidized outer surface of the billet flowing around the end of the billet and into the center of the bar during the final stages of extrusion. Also called *coring*.

**extrusion stock.** A rod, bar, or other section used to make extrusions.

**eyeletting.** The displacing of material about an opening in sheet or plate so that a lip protruding above the surface is formed.

## F

**fiber texture.** Crystallographic texture in which all or a large fraction of the crystals in a polycrystalline aggregate are oriented such that a specific direction in each crystal is parallel to a specific sample direction, such as the axis of symmetry of a cylindrical object. Often found in wrought products such as wire and round extrusions that have been subjected to large axisymmetric deformation.

**fillet.** The concave intersection of two surfaces. In forging, the desired radius at the concave intersection of two surfaces is usually specified.

**film strength.** The ability of a surface film to resist rupture by the penetration of asperities during sliding or rolling of two surfaces over each other.

**fin.** The thin projection formed on a forging by trimming or when metal is forced under pressure into hairline cracks or die interfaces.

**finish.** (1) The surface appearance of a product. (2) The forging operation in which the part is forged into its final shape in the finish die. If only one finish operation is scheduled to be performed in the finish die, this operation will be identified simply as finish; first, second, or third finish designations are so termed when one or more finish operations are to be performed in the same finish die.

**finish allowance.** The amount of excess metal surrounding the intended final shape; sometimes called clean-up allowance, forging envelope, or machining allowance.

**finisher (finishing impression).** The *die impression* that imparts the final shape to a forged part.

**finishing dies.** The die set used in the last forging step.

**finishing temperature.** The temperature at which *hot working* is completed.

**finish trim.** Flash removal from a forging; usually performed by trimming but sometimes by band sawing or similar techniques.

**finite element analysis (FEA), finite element modeling (FEM).** A computer-based technique for the analysis of an arbitrary part by breaking the problem into a mesh of simplified elements and then solving the corresponding system of equations, linear or nonlinear. FEA/FEM may be used to solve a wide variety of boundary-value problems of a material continuum, including responses to loads and temperatures.

**fire crack marks.** A network of raised irregular lines on the sheet surface produced by hot rolling with rolls containing thermal fatigue cracks in the surface.

**first block, second block, and finish.** The forging operation in which the part to be forged is passed in progressive order through three tools mounted in one forging machine; only one heat is involved for all three operations.

**first draw.** The first drawing operation in a series, which is usually performed on a flat blank.

**fishtail.** (1) In *roll forging*, the excess trailing end of a forging. Before being trimmed off, it is often used as a tong hold for a subsequent forging operation. (2) In hot *rolling* or *extrusion*, the imperfectly shaped trailing end of a bar or special section that must be cut off and discarded as mill scrap.

**fixture.** A tool or device for holding and accurately positioning a piece or part on a machine tool or other processing machine.

**flame hardening.** A heat treating method for surface hardening steel of the proper specifications in which an oxyacetylene flame heats the surface to a temperature at which subsequent cooling, usually with water or air, will give the required surface hardness.

**flame straightening.** The correction of distortion in metal structures by localized heating with a gas flame.

**flange.** A projecting rim or edge of a part; usually narrow and of approximately constant width for stiffening or fastening.

**flanging.** A bending operation in which a narrow strip at the edge of a sheet is bent down (up) along a straight or curved line. It is used for edge strengthening, appearance, rigidity, and the removal of sheared edges. A flange is often used as a fastening surface.

**flaring.** The forming of an outward acute-angle *flange* on a tubular part.

**flash.** Metal in excess of that required to completely fill the blocking or finishing forging impression of a set of dies. Flash extends out from the body of the forging as a thin protuberance at the line where the dies meet and is subsequently removed by trimming. Because it cools faster than the body of the component during forging, flash can serve to restrict metal flow at the line where dies meet, thus ensuring complete filling of the impression. See also *closed-die forging*.

**flash extension.** That portion of flash remaining on a forged part after trimming; usually included in the normal forging tolerances.

**flash land.** Configuration in the *blocking impression* or *finisher (finishing impression)* of forging dies designed to restrict or to encourage the growth of flash at the parting line, whichever may be required in a particular case to ensure complete filling of the impression.

**flash line.** The line left on a forging after the flash has been trimmed off.

**flash pan.** The machined-out portion of a forging die that permits the flow through of excess metal.

**flat-die forging.** See *open-die forging*.

**flattening.** (1) A preliminary operation performed on forging stock to position the metal for a subsequent forging operation. (2) The removal of irregularities or distortion in sheets or plates by a method such as *roller leveling* or *stretcher leveling*. (3) For wire, rolling round wire to a flattened condition.

**flattening dies.** Dies used to flatten sheet-metal hems; that is, dies that can flatten a bend by closing it. These dies consist of a top and bottom die with a flat surface that can close one section (flange) to another (hem, seam).

**fleck scale.** A fine pattern of scale marks on the sheet surface that can be either dark or light. The dark pattern originates from scale and other impurities embedded in the strip during hot rolling that are not removed during pickling. The light pattern originates from a scale pattern imprinted on the work rolls in the finishing stands in the hot mill being printed onto the strip.

**flex roll.** A movable roll designed to push up against a sheet as it passes through a roller lever. The flex roll can be adjusted to deflect the sheet any amount up to the roll diameter.

**flex rolling.** Passing sheets through a *flex roll* unit to minimize yield point elongation in order to reduce the tendency for *stretcher strains* to appear during forming.

**floating die.** (1) A die mounted in a die holder or a punch mounted in its holder such that a slight amount of motion compensates for tolerance in the die parts, the work, or the press. (2) A die mounted on heavy springs to allow vertical motion in some trimming, shearing, and forming operations.

**floating plug.** In tube drawing, an unsupported mandrel that locates itself at the die inside the tube, causing a reduction in wall thickness while the die is reducing the outside diameter of the tube.

**flop forging.** A forging in which the top and bottom die impressions are identical, permitting the forging to be turned upside down during the forging operation.

**flopers.** Lines or ridges that are transverse to the direction of rolling and generally confined to the section midway between the edges of the coil as rolled. They are somewhat irregular and tend toward a flat arc shape and are sometimes referred to as a shape wave.

**flow curve.** A curve of true stress versus true strain that shows the stress required to produce plastic deformation.

**flow lines.** (1) Texture showing the direction of metal flow during hot or cold working. Flow lines can often be revealed by etching the surface or a section of a metal part. (2) In mechanical metallurgy, paths followed by minute volumes of metal during deformation.

**flow localization.** A situation where material deformation is localized to a narrow zone. Such zones often are sites of failure. Flow localization results from poor lubrication, temperature gradients, or flow softening resulting from deformation heating, generation of softer crystallographic texture, grain coarsening, or spheroidization of second phases.

**flow softening.** Stress-strain behavior observed under constant strain-rate conditions characterized by decreasing flow stress with increasing strain. Flow softening may result from deformation heating as well as a number of microstructural sources, such as the generation of a softer crystallographic texture and the spheroidization of a lamellar phase.

**flow stress.** The uniaxial true stress required to cause plastic deformation at a particular value of strain, strain rate, and temperature.

**flow through.** A forging defect caused by metal flow past the base of a rib, with resulting rupture of the grain structure.

**fluid-cell process.** A modification of the *Guerin process* for forming sheet metal, the fluid-cell process uses higher pressure and is primarily designed for forming slightly deeper parts, using a rubber pad as either the die or punch. A flexible hydraulic fluid cell forces an auxiliary rubber pad to follow the contour of the form block and exert a nearly uniform pressure at all points on the workpiece. See also *fluid forming* and *rubber-pad forming*.

**fluid forming.** A modification of the *Guerin process*, fluid forming differs from the fluid-cell process in that the die cavity, called a pressure dome, is not completely filled with

rubber but with hydraulic fluid retained by a cup-shaped rubber diaphragm. See also *rubber-pad forming*.

**fluting.** A series of sharp parallel kinks or creases that can occur when sheet steel is formed cylindrically. Fluting is caused by inhomogeneous yielding of these sheets.

**flying shear.** A machine for cutting continuous rolled products to length that does not require a halt in rolling but rather moves along the runout table at the same speed as the product while performing the cutting, and then returns to the starting point in time to cut the next piece.

**flywheel.** A heavy rotating wheel, attached to a shaft, whose principal purpose is to store kinetic energy during the nonworking portion of a press cycle and to release energy during the working portion of a press cycle.

**flywheel press.** A mechanical power press in which the flywheel is mounted directly on the main crank or eccentric shaft without gearing.

**foil.** Metal in sheet form less than 0.15 mm (0.006 in.) thick.

**fold.** A forging defect caused by folding metal back onto its own surface during its flow in the die cavity.

**follow die.** A *progressive die* consisting of two or more parts in a single holder; used with a separate lower die to perform more than one operation (such as piercing and blanking) on a part in two or more stations.

**foot control.** A foot-operated control mechanism designed to be used with a clutch or clutch/brake control system on a press.

**foot pedal (treadle).** A foot-operated lever designed to operate the mechanical linkage that trips a full-revolution clutch on a press.

**forgeability.** Term used to describe the relative ability of material to deform without fracture. Also describes the resistance to flow from deformation. See also *formability*.

**forging.** The process of working metal to a desired shape by impact or pressure in hammers, forging machines (upsetters), presses, rolls, and related forming equipment. Forging hammers, counterblow equipment, and high-energy-rate forging machines apply impact to the workpiece, while most other types of forging equipment apply squeeze pressure in shaping the stock. Some metals can be forged at room temperature, but most are made more plastic for forging by heating. Specific forging processes defined in this Glossary include *closed-die forging*, *high-energy-rate forging*, *hot upset forging*, *isothermal forging*, *open-die forging*, *powder forging*, *precision forging*, *radial forging*, *ring rolling*, *roll forging*, *rotary forging*, and *rotary swaging*.

**forging billet.** A wrought metal slug used as *forging stock*.

**forging dies.** Forms for making forgings; they generally consist of a top and bottom die. The simplest will form a completed forging in a single impression; the most complex, consisting of several die inserts, may have a number of impressions for the progressive

working of complicated shapes. Forging dies are usually in pairs, with part of the impression in one of the blocks and the rest of the impression in the other block.

**forging envelope.** See *finish allowance*.

**forging machine (upsetter or header).** A type of forging equipment, related to the *mechanical press*, in which the principal forming energy is applied horizontally to the workpiece, which is gripped and held by prior action of the dies.

**forging plane.** In forging, the plane that includes the principal die face and is perpendicular to the direction of ram travel. When the parting surfaces of the dies are flat, the forging plane coincides with the parting line. Contrast with *parting plane*.

**forging quality.** Term used to describe stock of sufficient quality to make it suitable for commercially satisfactory forgings.

**forging rolls.** Power-driven rolls used in pre-forming bar or billet stock that have shaped contours and notches for introduction of the work.

**forging stock.** A wrought rod, bar, or other section suitable for subsequent change in cross section by forging.

**formability.** The ease with which a metal can be shaped through plastic deformation. Evaluation of the formability of a metal involves measurement of strength, ductility, and the amount of deformation required to cause fracture. The term *workability* is used interchangeably with formability; however, formability refers to the shaping of sheet metal, while workability refers to shaping materials by *bulk forming*. See also *forgeability*.

**formability parameters.** Material parameters that can be used to predict the ability of sheet metal to be formed into a useful shape.

**form block.** Tooling, usually the male part, used for forming sheet-metal contours; generally used in *rubber-pad forming*.

**form die.** A die used to change the shape of a sheet-metal blank with minimal plastic flow.

**forming.** The plastic deformation of a workpiece to obtain a desired configuration. The shape change takes place in the solid state and does not involve material removal or addition. Metal-forming processes are typically classified as *bulk forming* and *sheet forming*. Also referred to as metalworking.

**forming limit diagram (FLD) or forming limit curve (FLC).** An empirical curve in which the major strains at the onset of necking in sheet metal are plotted vertically and the corresponding minor strains are plotted horizontally. The onset-of-failure line divides all possible strain combinations into two zones: the safe zone (in which failure during forming is not expected) and the failure zone (in which failure during forming is expected). Also referred to as a Keeler-Goodwin diagram.

**form rolling.** Hot rolling to produce bars having contoured cross sections; not to be confused with the *roll forming* of sheet metal or with *roll forging*.

**forward extrusion.** Same as direct extrusion. See also *extrusion*.

**four-high mill.** A type of rolling mill, commonly used for flat-rolled mill products, in which two large-diameter backup rolls are employed to reinforce two smaller work rolls, which are in contact with the product. Either the work rolls or the backup rolls may be driven. Compare with *two-high mill* and *cluster mill*.

**fracture criterion.** A mathematical relationship among stresses, strains, or a combination of stresses and strains that predicts the occurrence of ductile fracture. Should not be confused with fracture mechanics equations, which deal with more brittle types of fracture.

**fracture limit line.** An experimental method for predicting surface fracture in plastically deformed solids. Is related to the forming limit diagram used to predict failures in sheet forming.

**fracture load.** The load at which splitting occurs.

**fracture-mechanism map.** Strain rate/temperature map that describes regimes under which different damage and failure mechanisms are operative under either forming or service conditions.

**fracture strain ( $\epsilon_f$ ).** The true strain at fracture defined by the relationship:

$$\epsilon_f = \ln \left[ \frac{\text{Initial cross-sectional area}}{\text{Final cross-sectional area}} \right]$$

**fracture strength.** The engineering stress at fracture, defined as the load at fracture divided by the original cross-sectional area. The fracture strength is synonymous with the breaking strength.

**fracture stress.** The true stress at fracture, which is the load for fracture divided by the final cross-sectional area.

**frame.** The main structure of a *press*.

**free bending.** A bending operation in which the sheet metal is clamped at one end and wrapped around a radius pin. No tensile force is exerted on the ends of the sheet.

**free forming.** Bending over a die or shape in which the metal being bent is not considered.

**friction.** The resisting force tangential to the common boundary between two bodies when, under the action of an external force, one body moves or tends to move relative to the surface of the other.

**friction coextrusion.** Extrusion process for a solid core along with a tube made of a cladding material.

**friction extrusion.** A rotating round bar is pressed against a die to produce sufficient frictional heating to allow softened material to extrude through the die.

**friction gouges.** Line-type defects resulting from sliding sheet metal as in slipping of windings within a coil of steel. See also *scoring*.

**friction hill.** Shape of the normal pressure-position plot that pertains to the axisymmetric and plane-strain forging of simple and

complex shapes. The pressure is approximately equal to the flow stress at the edge of the forging and increases toward the center, thus producing the characteristic hilllike shape. The exact magnitude of the increase in pressure is a function of interface friction and the diameter-to-thickness or width-to-thickness ratio of the forging.

**friction shear factor.** Interface friction coefficient for which the interface shear stress is taken to be proportional to the flow stress divided by  $\sqrt{3}$ . The proportionality constant is called the friction shear factor (or interface friction factor) and is usually denoted as *m*. The friction shear factor takes on values between 0 (perfect lubrication) and 1 (sticking friction) during metalworking. See also *Coulomb friction*.

**front and back plate press.** A type of hydraulic press in which the crown and bed are positioned and retained by steel plate strain members, front and back. Single rectangular openings are cut in both plates to provide entry to the work area.

**Fukui cup test.** A cupping test combining stretchability and drawability in which a round-nosed punch draws a circular blank into a conical-shaped die until fracture occurs at the nose. Various parameters from the test are used as the criterion of formability.

**fuller (fullering impression).** Portion of the die used in hammer forging primarily to reduce the cross section and lengthen a portion of the forging stock. The fullering impression is often used in conjunction with an *edger* (*edging impression*).

## G

**gage.** (1) The thickness of sheet or the diameter of wire. The various standards are arbitrary and differ with regard to ferrous and non-ferrous products as well as sheet and wire. (2) An aid for visual inspection that enables an inspector to determine more reliably whether the size or contour of a formed part meets dimensional requirements.

**galling.** A condition whereby excessive friction between high spots results in localized welding with subsequent spalling and further roughening of the rubbing surface(s) of one or both of two mating parts.

**gap-frame press.** A general classification of press in which the uprights or housings are made in the form of a letter "C," thus making three sides of the die space accessible.

**gate or movable-barrier device.** A movable barrier arranged to enclose the point of operation before a press stroke can be started.

**geared press.** A press whose main crank or eccentric is connected to the driving source by one or more sets of gears.

**gibs.** Guides or shoes that ensure the proper parallelism, squareness, and sliding fit between press components such as the slide

and the frame. They are usually adjustable to compensate for wear and to establish operating clearance.

**grain.** An individual crystal in a polycrystalline metal or alloy.

**grain boundary.** The boundary between adjacent crystals/grains in a polycrystalline aggregate.

**grain-boundary sliding.** The sliding of grains past each other that occurs at high temperature. Grain-boundary sliding is common under creep conditions in service, thus leading to internal damage (e.g., cavities) or total failure, and during superplastic forming, in which undesirable cavitation may also occur if diffusional or deformation processes cannot accommodate the stress concentrations associated with sliding at a sufficient rate.

**grain growth.** The increase in the average size of grains in a crystalline aggregate during annealing (static conditions) or deformation (dynamic conditions). The driving force for grain growth is the reduction in total grain-boundary area and its associated surface energy.

**grain size.** A measure of the area or volume of grains in a polycrystalline material, usually expressed as an average when the individual sizes are fairly uniform.

**gravity hammer.** A class of forging hammer in which energy for forging is obtained by the mass and velocity of a freely falling ram and the attached upper die. Examples are the *board hammer* and *air-lift hammer*.

**grease pits.** Shallow, dark-colored depressions in the strip surface caused by the adhesion of grease, carbon, and so on to the work roll surface.

**green.** Unsintered (not sintered).

**green compact.** An unsintered *compact*.

**green strength.** (1) The ability of a *green compact* to maintain its size and shape during handling and storage prior to *sintering*. (2) The tensile or compressive strength of a green compact.

**gridding.** Imprinting an array of repetitive geometrical patterns on a sheet prior to forming for subsequent determination of deformation. Imprinting techniques include: (1) Electrochemical marking (also called electrochemical or electrolytic etching)—a grid-imprinting technique using electrical current, an electrolyte, and an electrical stencil to etch the grid pattern into the blank surface. A contrasting oxide usually is redeposited simultaneously into the grid. (2) Photoprint—a technique in which a photosensitive emulsion is applied to the blank surface, a negative of the grid pattern is placed in contact with the sheet, and the pattern is transferred to the sheet by a standard photographic printing practice. (3) Ink stamping. (4) Lithographing.

**gripper dies.** The lateral or clamping dies used in a forging machine or mechanical upsetter.

**groove.** In *deep drawing*, the mating depression for the *drawbead*.

**guard.** A barrier that prevents entry of a press operator's hands or fingers into the point of operation.

**Guerin process.** A *rubber-pad forming* process for forming sheet metal.

**guide.** The parts of a drop hammer or press that guide the up-and-down motion of the ram in a true vertical direction.

**guided bend test.** A test in which the specimen is bent to a definite inside radius of a jig.

**guide pin bushings.** Bushings, pressed into a die shoe, that allow the *guide pins* to enter in order to maintain punch-to-die alignment.

**guide pins.** Hardened, ground pins or posts that maintain alignment between punch and die during die fabrication, setup, operation, and storage. If the press slide is out of alignment, the guide pins cannot make the necessary correction unless heel plates are engaged before the pins enter the bushings. See also *heel block*.

**gutter.** A depression around the periphery of a forging *die impression* outside the *flash pan* that allows space for the excess metal; surrounds the finishing impression and provides room for the excess metal used to ensure a sound forging. A shallow impression outside the parting line.

## H

**Hall-Petch dependence.** A measure of the effect of grain size on the yield strength of a metal. Typically, the yield strength is inversely proportional to the square root of the grain size.

**hammer.** A machine that applies a sharp blow to the work area through the fall of a ram onto an anvil. The ram can be driven by gravity or power. See also *gravity hammer* and *power-driven hammer*.

**hammer forging.** Forging in which the work is deformed by repeated blows. Compare with *press forging*.

**hammering.** The working of metal sheet into a desired shape over a form or on a high-speed hammer and a similar anvil to produce the required dishing or thinning.

**hand forge (smith forge).** A forging operation in which forming is accomplished on dies that are generally flat. The piece is shaped roughly to the required contour with little or no lateral confinement; operations involving mandrels are included. The term *hand forge* refers to the operation performed, while hand forging applies to the part produced.

**hand straightening.** A straightening operation performed on a surface plate to bring a forging within straightness tolerance. A bottom die from a set of finish dies is often used instead of a surface plate. Hand tools used include mallets, sledges, blocks, jacks, and oil gear presses in addition to regular inspection tools.

**hardness test.** A test to measure the resistance to indentation of a material. Tests for sheet metal

include Rockwell, Rockwell Superficial, Tukon, and Vickers.

**Hartmann lines.** See *Lüders lines*.

**header.** See *forging machine (upsetter or header)*.

**heading.** The *upsetting* of wire, rod, or bar stock in dies to form parts that usually contain portions that are greater in cross-sectional area than the original wire, rod, or bar.

**healed-over scratch.** A scratch that occurred during previous processing and that was partially obliterated in subsequent rolling.

**heel block.** A block or plate usually mounted on or attached to a lower die that serves to prevent or minimize the deflection of punches or cams.

**hemming.** A bend of 180° made in two steps. First, a sharp-angle bend is made; next, the bend is closed using a flat punch and a die.

**HERF.** A common abbreviation for *high-energy-rate forging* or *high-energy-rate forming*.

**high-angle boundary.** Boundary separating adjacent grains whose misorientation is at least 15°.

**high-energy-rate forging.** The production of forgings at extremely high ram velocities resulting from the sudden release of a compressed gas against a free piston. Forging is usually completed in one blow. Also known as HERF processing, high-velocity forging, and high-speed forging.

**high-energy-rate forming.** A group of forming processes that applies a high rate of strain to the material being formed through the application of high rates of energy transfer. See also *explosive forming*, *high-energy-rate forging*, and *electromagnetic forming*.

**holddown plate (pressure pad).** A pressurized plate designed to hold the workpiece down during a press operation. In practice, this plate often serves as a *stripper* and is also called a stripper plate.

**hole expansion.** Forcing the metal around a hole out from the sheet surface.

**hole expansion test.** A formability test in which a tapered punch is forced through a punched or a drilled and reamed hole, forcing the metal in the periphery of the hole to expand in a stretching mode until fracture occurs.

**hole flanging.** The forming of an integral collar around the periphery of a previously formed hole in a sheet-metal part.

**Hollomon hardening.** See *power-law hardening*.

**homogenization.** Heat treatment used to reduce or eliminate nonuniform chemical composition that develops on a microscopic scale (microsegregation) during the solidification processing of ingots and castings. Homogenization is commonly used for aluminum alloys and nickel-base superalloys.

**Hooke's law.** Stress-strain behavior for a material in which the stress is linearly proportional to strain. See also *modulus of elasticity*.

**hot brake forming.** A forming process where the blank is heated up and formed in a cold tool. This is usually done very quickly, and the

springback in the material is similar to a cold forming.

**hot forming.** See *hot working*. Similar to hot sizing; however, the forming is done at temperatures above the annealing temperature, and deformation is usually larger.

**hot isostatic pressing (HIP).** A process for simultaneously heating and forming a powder metallurgy compact in which metal powder, contained in a sealed flexible mold, is subjected to equal pressure from all directions at a temperature high enough for full consolidation to take place. Hot isostatic pressing is also frequently used to seal residual porosity in castings and to consolidate metal-matrix composites.

**hot mill gouges.** A series of short scratches caused by slippage of one surface of a coil relative to another during hot coiling.

**hot rolled sheet.** Steel sheet reduced to required thickness at a temperature above the point of scaling and therefore carrying hot mill oxide. The sheet may be flattened by cold rolling without appreciable reduction in thickness or by roller leveling, or both. Depending on the requirements, hot rolled sheet can be pickled to remove hot mill oxide and is so produced when specified.

**hot shortness.** A tendency for some alloys to separate along grain boundaries when stressed or deformed at temperatures near the melting point. Hot shortness is caused by a low-melting constituent, often present only in minute amounts, that is segregated at grain boundaries.

**hot size.** A process where a preformed part is placed into a hot die above the annealing temperature to set the shape and remove springback tendencies.

**hot strip or pickle line scratch.** Scratches that are superficially similar to slivers or skin laminations but originate from mechanical scoring of the strip in the hot mill, pickle line, or slitter.

**hot trimming.** The removal of *flash* or excess metal from a hot part (such as a forging) in a trimming press.

**hot upset forging.** A *bulk forming* process for enlarging and reshaping some of the cross-sectional area of a bar, tube, or other product form of uniform (usually round) section. It is accomplished by holding the heated forging stock between grooved dies and applying pressure to the end of the stock, in the direction of its axis, by the use of a heading tool, which spreads (upsets) the end by metal displacement. Also called hot heading or hot upsetting. See also *heading* and *upsetting*.

**hot working.** The plastic deformation of metal at such a temperature and strain rate that recrystallization or a high degree of recovery takes place simultaneously with the deformation, thus avoiding any *strain hardening*. Also referred to as hot forging and hot forming. Contrast with *cold working*.

**hourglassing.** A problem with some finite elements and some loading conditions where an

element appears to be much less stiff than the actual material. The computed loads can thus be much lower than the true ones, or the computed strains can be much lower. The label refers to the appearance of the deformed finite element mesh that is sometimes observed where adjacent elements deform oppositely.

**housing press.** A type of hydraulic press in which the crown and bed are separated by uprights or spaces extending from front to back through which strain rods pass.

**hub.** A boss that is in the center of a forging and forms a part of the body of the forging.

**hubbing.** The production of die cavities by pressing a male master plug, known as a *hub*, into a block of metal.

**hydraulic hammer.** A gravity-drop forging hammer that uses hydraulic pressure to lift the hammer between strokes.

**hydraulic-mechanical press brake.** A mechanical *press brake* that uses hydraulic cylinders attached to mechanical linkages to power the ram through its working stroke.

**hydraulic press.** A press in which fluid pressure is used to actuate and control the ram.

**hydraulic press brake.** A *press brake* in which the ram is actuated directly by hydraulic cylinders.

**hydraulic shear.** A shear in which the crosshead is actuated by hydraulic cylinders.

**hydrodynamic lubrication.** A system of lubrication in which the shape and relative motion of the sliding surfaces causes the formation of a liquid film having sufficient pressure to separate the surfaces. See also *elastohydrodynamic lubrication*.

**hydrostatic extrusion.** A method of extruding a *billet* through a die by pressurized fluid instead of the ram used in conventional *extrusion*.

**hydrostatic stress.** The average value of the three normal stresses. The hydrostatic stress is a quantity that is invariant relative to the orientation of the coordinate system in which the stress state is defined.

## I

**IACS.** See *percent IACS (%IACS)*.

**impact extrusion.** The process (or resultant product) in which a punch strikes a slug (usually unheated) in a confining die. The metal flow may be either between punch and die or through another opening. The impact extrusion of unheated slugs is often called cold extrusion.

**impact line.** A blemish on a drawn sheet-metal part caused by a slight change in metal thickness. The mark is called an impact line when it results from the impact of the punch on the blank; it is called a recoil line when it results from transfer of the blank from the die to the punch during forming, or from a reaction to the blank being pulled sharply through the *draw ring*.

**implicit.** A type of finite element algorithm where a trial solution is proposed, the errors computed, and a better solution is proposed until a satisfactory solution is obtained. Accuracy can be ensured by such a method, but convergence to an answer cannot. Typical sheet-forming programs of this type do not consider momentum effects and thus are often called static explicit programs.

**impression.** A cavity machined into a forging die to produce a desired configuration in the workpiece during forging.

**impression-die forging.** See *closed-die forging*.

**inclined press.** A small- or medium-sized press that may be inclined (tilted backward) to facilitate ejection of finished parts by gravity. Such presses are usually of the open-back, gap-frame type with right-to-left crankshaft. They are built in a maximum size of approximately 200 tons. They may be, and very often are, used in the upright or vertical position, being readily adjustable, usually by a hand mechanism, to any desired inclination up to the usual maximum of 45°.

**increase in area.** An indicator of sheet-metal-forming severity based on percentage increase in surface area measured after forming.

**indirect (backward) extrusion.** See *extrusion*.

**ingot.** A casting intended for subsequent rolling, forging, or extrusion.

**ingot conversion.** A primary metalworking process that transforms a cast ingot into a wrought mill product.

**ingot metallurgy.** A processing route consisting of casting an ingot that is subsequently converted into mill products via deformation processes.

**integration point.** Location in a finite element that is used to integrate over the volume in an approximate way to obtain the work of deformation of the element as a whole. For shell elements, the integration points through the thickness are used to obtain the sheet tension and moment by integration, with more integration points providing a better approximation to the true integral values.

**interface heat-transfer coefficient (IHTC).** Coefficient defined as the ratio of the heat flux across an interface to the difference in temperature of material points lying on either side of the interface. In bulk forming, the IHTC is usually a function of the die and workpiece surface conditions, lubrication, interface pressure, amount of relative sliding, and so on.

**intermetallic alloy.** A metallic alloy usually based on an ordered, stoichiometric compound (e.g., Fe<sub>3</sub>Al, Ni<sub>3</sub>Al, TiAl) and often possessing exceptional strength and environmental resistance at high temperatures, unlike conventional (less highly alloyed) disordered metallic materials.

**ironing.** An operation used to increase the length of a tube or cup through reduction of wall thickness and outside diameter, the inner diameter remaining unchanged.

**isostatic pressing.** A process for forming a powder metallurgy compact/metal-matrix

composite or for sealing casting porosity by applying pressure equally from all directions. See also *hot isostatic pressing (HIP)*.

**isothermal forging.** A hot forging process in which a constant and uniform temperature is maintained in the workpiece during forging by heating the dies to the same temperature as the workpiece.

**isotropy.** A term indicating equal physical or mechanical properties in all directions.

## J

**Joffé effect.** Change in mechanical properties, especially the fracture strength, resulting from testing in an environment that modifies the surface characteristics of the material.

**jog.** An intermittent motion imparted to a press side by momentary operation of the drive motor, after the clutch is engaged with the flywheel at rest.

**joggle.** (1) An offset (usually with parallel surfaces) in the surface of a sheet or part. (2) The process or act of offsetting the surface of a plate or part.

## K

**Keeler-Goodwin diagram.** See *forming limit diagram (FLD) or forming limit curve (FLC)*.

**kinetics.** Term describing the rate at which a metallurgical process (e.g., recovery, recrystallization, grain growth, phase transformation) occurs as a function of time or, if during deformation, of strain.

**kinks.** Sharp bends or buckles caused by localized plastic deformation of a sheet.

**klink.** An internal crack caused by too rapid heating of a large workpiece.

**knockout.** A mechanism for releasing workpieces from a die.

**knockout, hydraulic.** On a hydraulic press, a mechanism actuated by a hydraulic cylinder for the purpose of ejecting work from the tools.

**knockout mark.** A small protrusion, such as a button or ring of flash, resulting from depression of the *knockout pin* from the forging pressure or the entrance of metal between the knockout pin and the die.

**knockout, mechanical.** A mechanism actuated by a hydraulic-press slide on its return stroke and arranged to eject work from the tools.

**knockout pin.** A power-operated plunger installed in a die to aid removal of the finished forging.

**knockout, pneumatic.** On a hydraulic press, a mechanism actuated by a pneumatic cylinder for the purpose of ejecting work from the tools.

**knuckle-joint press.** A press in which the slide is directly actuated by a single toggle (or knuckle) joint, which is closed and opened by means of a connection and a crank.

## L

**lancing.** Cutting along a line in the workpiece without detaching a slug from the blank.

**laser cutting.** A cutting process that severs material with the heat obtained by directing a laser beam against a metal surface. The process can be used with or without an externally supplied shielding gas.

**lateral extrusion.** An operation in which the product is extruded sideways through an orifice in the container wall.

**lattice.** A regular geometrical arrangement of points in space. See also *point lattice* and *space lattice*.

**lattice constants.** See *lattice parameter*.

**lattice parameter.** The length of any side of a unit cell of a given crystal structure. The term is also used for the fractional coordinates  $x$ ,  $y$ ,  $z$  of lattice points when these are variable.

**leveler breaks.** Parallel surface markings perpendicular to the rolling direction caused by localized discontinuous yielding of the metal due to flexing during leveling.

**leveler lines.** Lines on sheet or strip running transverse to the direction of *roller leveling*. These lines may be seen upon stoning or light sanding after leveling (but before drawing) and can usually be removed by moderate stretching.

**leveling.** The flattening of rolled sheet, strip, or plate by reducing or eliminating distortions. See also *stretcher leveling* and *roller leveling*.

**liftout.** The mechanism also known as *knockout*.

**limiting drawing ratio (LDR).** See *deformation limit*.

**linear element.** A finite element that assumes that the pattern of displacements inside the element varies linearly with position inside the element.

**liners.** Thin strips of metal inserted between the dies and the units into which the dies are fastened.

**lock.** In forging, a condition in which the flash line is not entirely in one plane. Where two or more plane changes occur, it is called compound lock. Where a lock is placed in the die to compensate for die shift caused by a steep lock, it is called a counterlock.

**lockhead.** A ridge constructed around a die cavity to completely restrict metal flow into the die.

**locked dies.** Dies with mating faces that lie in more than one plane.

**locking.** A problem with some finite elements and some loading conditions where an element appears to be much stiffer than the actual material. The computed loads can thus be much higher than the true ones, or the computed strains can be much lower.

**loop press.** A type of hydraulic press in which the crown and bed are separated by straight-side members that are an integral part of an oval-shaped continuous band.

**loose metal.** A defect in an area of a stamping where very little contour is present. The metal

in the area has not been stretched, resulting in a shape with no stiffness. The area may have waves in it or may sag so that there is a dish in an area that is intended to be flat or nearly flat. This defect differs from oil canning in that the metal cannot be snapped back into the desired shape when a load is removed or reversed on the area.

**low-angle boundary.** Boundary separating adjacent grains whose misorientation is less than  $15^\circ$ . See also *subgrain*.

**lower punch.** The lower part of a die that forms the bottom of the die cavity and that may or may not move in relation to the die body; usually movable in a forging die.

**lubricant.** A material applied to dies, molds, plungers, or workpieces that promotes the flow of metal, reduces friction and wear, and aids in the release of the finished part.

**lubricant carrier.** A coating, such as a phosphate or lime, used to increase the amount of lubricant available at a loaded interface.

**lubricant residue.** The carbonaceous residue resulting from lubricant that is burned onto the surface of a hot forged part.

**Lüders lines.** Elongated surface markings or depressions, often visible with the unaided eye, that form along the length of a round or sheet-metal tension specimen at an angle of approximately  $55^\circ$  to the loading axis. Caused by localized plastic deformation, they result from discontinuous (inhomogeneous) yielding. Also known as Lüders bands, Hartmann lines, Piobert lines, or stretcher strains.

## M

**major strain.** Largest principal strain. For sheet-forming applications, it is often measured from the major axis of the ellipse resulting from deformation of a circular grid printed on the sheet surface.

**mandrel.** (1) A blunt-ended tool or rod used to retain the cavity in a hollow metal product during working. (2) A metal bar around which other metal can be cast, bent, formed, or shaped. (3) A shaft or bar for holding work to be machined.

**mandrel forging.** The process of rolling or forging a hollow blank over a mandrel to produce a weldless, seamless ring or tube.

**manipulator.** A mechanical device for handling an ingot, billet, or bar during forging. See also *chuckhead*.

**Mannesmann process.** A process for piercing tube billets in making seamless tubing. The billet is rotated between two heavy rolls mounted at an angle and is forced over a fixed mandrel.

**Marforming process.** A *rubber-pad forming* process developed to form wrinkle-free shrink flanges and deep-drawn shells. It differs from the *Guerin process* in that the sheet-metal blank is clamped between the rubber pad and the blankholder before forming begins.

**master block.** A forging *die block* used primarily to hold insert dies. See also *die insert*.

**match.** A condition in which a point in one die half is aligned properly with the corresponding point in the opposite die half, within specified tolerance.

**matched edges (match lines).** Two edges of the die face that are machined exactly at 90° to each other and from which all dimensions are taken in laying out the die impression and aligning the dies in the forging equipment.

**matching draft.** The adjustment of draft angles (usually involving an increase) on parts with asymmetrical ribs and sidewalls to make the surfaces of a forging meet at the parting line.

**material heat.** The pedigree of the starting stock or billet used to make a forging.

**matrix phase.** The continuous (interconnected) phase in an alloy with two or more phases. In cast or wrought materials, the matrix phase is often comprised of the first phase to solidify.

**mechanical press.** A forging press with an inertia flywheel, a crank and clutch, or other mechanical device to operate the ram.

**mechanical press brake.** A *press brake* using a mechanical drive consisting of a motor, flywheel, crankshaft, clutch, and eccentric to generate vertical motion.

**mechanical texture.** Directionality in the shape and orientation of microstructural features such as inclusions, grains, and so on.

**mechanical upsetter.** A three-element forging press, with two gripper dies and a forming tool, for flanging or forming relatively deep recesses.

**mechanical working.** The subjecting of material to pressure exerted by rolls, hammers, or presses in order to change the shape or physical properties of the material.

**membrane strain.** The strain at the center of a cross section of a bent beam or sheet. It is also the average strain of that cross section for an assumed linear bending strain through the thickness.

**microalloyed steel.** A low-to-medium-carbon steel usually containing small alloying additions of niobium, vanadium, nitrogen, and so on whose thermomechanical processing is controlled to obtain a specific microstructure and thus a suite of properties. See also *controlled rolling*.

**microhardness test.** An indentation test using diamond indentors at very low loads, usually in the range of 1 to 1000 g.

**microstructure.** The structure of polished and etched metals as revealed by a microscope.

**mill.** (1) A factory in which metals are hot worked, cold worked, or melted and cast into standard shapes suitable for secondary fabrication into commercial products. (2) A production line, usually of four or more *stands*, for hot or cold rolling metal into standard shapes such as bar, rod, plate, sheet, or strip. (3) A single machine for hot rolling, cold rolling, or extruding metal; examples include *blooming mill*, *cluster mill*, *four-high mill*, and *Senzimir mill*. (4) A shop term for a milling

cutter. (5) A machine or group of machines for grinding or crushing ores and other minerals.

**mill digs.** A defect caused by the slippage of the coil surface on the adjacent wrapped surface, sometimes caused by the use of extreme back tension and sometimes by the failure of the mandrel to grip the coil firmly due to damage of the internal wraps. Mill digs vary considerably in appearance from short, light scratches to, in extreme cases, holes in the sheet surface.

**mill edge.** The normal edge produced in rolling. Can be contrasted with a blanked or sheared edge that has a *burr*.

**mill finish.** A nonstandard (and typically non-uniform) surface finish on mill products that are delivered without being subjected to a special surface treatment (other than a corrosion-preventive treatment) after the final working or heat treating step.

**mill product.** Any commercial product of a *mill*.

**mill scale.** The heavy oxide layer that forms during the hot fabrication or heat treatment of metals.

**minimum bend radius.** The smallest radius about which a metal can be bent without exhibiting fracture. It is often described in terms of multiples of sheet thickness.

**minor strain.** Either of the two smaller principal strains. For sheet-forming applications, it is often measured from the minor axis of the ellipse resulting from deformation of a circular grid printed on the sheet surface.

**mischmetal.** From the German *mischmetall*, with roots *mischen* (to mix) and *metall* (metal), it is a natural mixture of rare earth metals containing approximately 50 wt% Ce, 25% La, 15% Nd, and 10% other rare earth metals, iron and silicon. It is commonly used to make rare earth additions to alloys (e.g., magnesium alloys), rather than using more expensive pure forms of the rare earth metals.

**mismatch.** The misalignment or error in register of a pair of forging dies; also applied to the condition of the resulting forging. The acceptable amount of this displacement is governed by blueprint or specification tolerances. Within tolerances, mismatch is a condition; in excess of tolerance, it is a serious defect. Defective forgings can be salvaged by hot reforging operations.

**misorientation.** Angular difference between the orientations of two grains adjacent to a grain boundary, between a twin and its parent matrix, and so on.

**mixed dislocation.** Any combination of a *screw dislocation* and an *edge dislocation*.

**modulus of elasticity,  $E$ .** The measure of rigidity or stiffness of a metal; the ratio of stress, below the proportional limit, to the corresponding strain. In terms of the *stress-strain diagram*, the modulus of elasticity is the slope of the stress-strain curve in the range of linear proportionality of stress to strain. Also known as *Young's modulus*. For materials that do not conform to *Hooke's law* throughout the elastic range, the slope of either

the tangent to the stress-strain curve at the origin or at low stress, the secant drawn from the origin to any specified point on the stress-strain curve, or the chord connecting any two specific points on the stress-strain curve is usually taken to be the modulus of elasticity. In these cases, the modulus is referred to as the *tangent modulus*, *secant modulus*, or *chord modulus*, respectively.

**moment of inertia.** A measure of the ability of a beam or sheet to resist bending. It is a geometric property of the body and depends on a reference axis. The smallest moment of inertia is the one of interest; its reference axis passes through the centroid of the section. The area moment of inertia may be found by integrating  $x^2 dA$  over the cross section, where  $x$  is the distance from the reference axis, and  $dA$  is the differential area of the beam at that distance.

**Monte-Carlo modeling.** Numerical modeling technique, based on statistical mechanics, that can be used to describe the migration of grain boundaries in polycrystalline aggregates during annealing or deformation processes and thus is applied to describe recrystallization, grain growth, and the accompanying evolution of texture. Also referred to as the Potts technique.

**multiple.** A piece of stock for forging that is cut from bar or billet lengths to provide the exact amount of material needed for a single work-piece. Also sometimes referred to as *mult*.

**multiple-slide press.** A press with individual slides, built into the main slide or connected to individual eccentrics on the main shaft, that can be adjusted to vary the length of stroke and the timing. See also *slide*.

**$m$ -value.** See *strain-rate sensitivity*.

## N

**natural draft.** Taper on the sides of a forging, due to its shape or position in the die, that makes added draft unnecessary.

**near-net shape forging.** A forging produced with a very small finish allowance over the final part dimensions and requiring some machining prior to use.

**necking.** (1) The reduction of the cross-sectional area of metal in a localized area by uniaxial tension or by stretching. (2) The reduction of the diameter of a portion of the length of a cylindrical shell or tube.

**necklace recrystallization.** Partial static or dynamic recrystallization that nucleates heterogeneously on grain boundaries in various steels, nickel-base superalloys, and so on. A microstructure of fine (necklace-like) grains lying on the original grain boundaries is thus produced.

**net shape forging.** A forging produced to finished part dimensions that requires little or no further machining prior to use.

**neural network.** Nonlinear regression-type methodology for establishing the correlation

between input and output variables in a physical system. For example, neural networks can be used to correlate processing variables to microstructural features or microstructural features to mechanical properties.

**neuron.** A node in a neural network system that can be considered as an internal variable and whose value is a function of the neurons in the previous layer.

**neutral axis.** The stress-free location in a beam or sheet subjected to bending and possibly sheet tension or compression. It may be located outside of the sheet; for pure bending, it is located at the center of the sheet. For simple cases, the neutral axis is assumed to coincide with the axis of zero extension.

**node.** A point of a finite element where variables such as location and force are monitored and solved for. Adjacent elements share common nodes, thus ensuring an approximation of compatibility.

**no-draft (draftless) forging.** A forging with extremely close tolerances and little or no draft that requires minimal machining to produce the final part. Mechanical properties can be enhanced by closer control of grain flow and by retention of surface material in the final component.

**nominal strain.** The unit elongation given by the change in length divided by the original length. Also called engineering strain.

**nominal stress.** The stress obtained when the applied load is divided by the original cross-sectional area. Also called engineering stress.

**nonfill (underfill).** A forging condition that occurs when the die impression is not completely filled with metal.

**normal anisotropy.** A condition in which a property or properties in the sheet thickness direction differ in magnitude from the same property or properties in the plane of the sheet.

**notching.** An unbalanced shearing or blanking operation in which cutting is done around only three sides (usually) of a punch.

***n*-value.** See *strain-hardening exponent*.

## O

**objective function.** Mathematical function describing a desired material or process characteristic whose optimization is the goal of process design. In bulk forming, typical objective functions may include forging weight (minimum usually is best), die fill (minimum underfill is best), and uniformity of strain or strain rate (maximum uniformity is best).

**offal.** Sheet-metal section trimmed or removed from the sheet during the production of shaped blanks or the formed part. Offal is frequently used as stock for the production of small parts.

**offset.** A specified distance along the strain coordinate between the initial portion of a stress-strain curve that is used to define one measure of yield stress. A line parallel to

the initial elastic portion of the stress-strain curve is drawn offset by the specified strain, typically 0.2%. The intersection of this line and the stress-strain curve defines the *yield strength*. The offset yield stress is often used for materials that have no obvious *yield point*.

**offset yield strength.** A measure of yield stress determined by the intersection of a line parallel to the initial elastic portion of the stress-strain curve offset from the origin by the specified strain, typically 0.2%.

**oil canning.** Same as *canning*.

**Olsen ductility test.** A *cupping test* in which a piece of sheet metal, restrained except at the center, is deformed by a standard steel ball until fracture occurs. The height of the cup at the time of fracture is a measure of the ductility.

**open-back inclinable (OBI) press.** A gap-frame press with an opening at the back between the two side members of the frame and arranged to be inclinable to facilitate part removal by gravity. See also *inclinable press*.

**open-back stationary (OBS) press.** A gap-frame press with an opening at the back between the two side members of the frame and arranged to be upright or permanently inclined.

**open die.** Die with a flat surface that is used for preforming stock or producing hand forgings.

**open-die forging.** The hot mechanical forming of metals between flat or shaped dies in which metal flow is not completely restricted. Also known as hand or smith forging. See also *hand forge* (*smith forge*).

**open-rod press.** A type of hydraulic press in which the crown and bed are positioned and retained by strain rods.

**orange peel.** A roughened or pebbly surface condition evident after substantial deformation that occurs with sheet metal, having an exceedingly coarse grain size. It should not be confused with a similar roughened surface resulting from fine stretcher strains.

**orbital forging.** See *rotary forging*.

**orientation-distribution function (ODF).** Mathematical function describing the normalized probability of finding grains of given crystallographic orientations/Euler angles. Because crystallographic orientations are in terms of Euler angles, the description of texture using ODFs is unambiguous, unlike pole figures. See also *texture*, *preferred orientation*, and *pole figure*.

**Ostwald ripening.** The increase in the average size of second-phase particles, accompanied by the reduction in their number, during annealing, deformation, or high-temperature service exposure. Ostwald ripening leads to a decrease in the total surface energy associated with matrix-particle interfaces. Also known as *coarsening*.

**oxidation.** A reaction where there is an increase in valence resulting from a loss of electrons. Such a reaction occurs when most metals or alloys are exposed to atmosphere, and

the reaction rate increases as temperature increases.

**oxidized surface.** A tightly adhering oxide surface layer that results in modified surface color and reduced reflectivity. It is often accompanied by surface penetration of oxide that causes brittleness.

## P

**pack rolling.** Hot, flat rolling process in which the workpiece (or a stack of workpieces) in the form of plate, sheet, or foil is encased in a sacrificial can to reduce/eliminate contamination (e.g., oxygen pickup) or poor workability due to roll chill.

**pad.** The general term used for that part of a die that delivers holding pressure to the metal being worked.

**pad holder.** Container for a rubber pad on a hydraulic press.

**pancake forging.** A rough forged shape, usually flat, that can be obtained quickly with minimal tooling. Usually made by upsetting a cylindrical billet to a large height reduction in flat dies. Considerable machining is usually required to attain the finish size.

**parting.** A shearing operation used to produce two or more parts from a stamping.

**parting line.** The line along the surface of a forging where the dies meet, usually at the largest cross section of the part. *Flash* is formed at the parting line.

**parting plane.** The plane that includes the principal die face and is perpendicular to the direction of ram travel. When parting surfaces of the dies are flat, the parting plane coincides with the parting line. Also referred to as the *forging plane*.

**pass.** (1) A single transfer of metal through a *stand* of rolls. (2) The open space between two grooved rolls through which metal is processed.

**peak count.** In surface measurements, the number of asperities above a given (defined) height cut-off level and within a given width cut-off. Frequency is taken at 50  $\mu\text{in./in.}$

**peak density.** The average number of peaks within the specified cut-off levels.

**peak height.** Peak-to-valley magnitude as measured by a suitable stylus instrument. Peak height is related to roughness height, depending on uniformity of surface irregularities.

**peen forming.** A dieless, flexible-manufacturing technique used primarily in the aerospace industry for forming sheet metals by way of the deformation imparted by the controlled-velocity impact of balls.

**percent IACS (%IACS).** In 1913, values of electrical conductivity were established and expressed as a percent of a standard. The standard chosen was an annealed copper wire with a density of 8.89 g/cm<sup>3</sup>, a length of 1 m, a weight of 12 g, with a resistance of 0.1532  $\Omega$

at 20 °C (70 °F). The 100% IACS (International Annealed Copper Standard) value was assigned with a corresponding resistivity of  $0.017241 \Omega\text{mm}^2/\text{m}$ . The percent IACS for any material can be calculated by  $\% \text{IACS} = 0.017241 \Omega\text{mm}^2/\text{m} \times 100/\text{volume resistivity}$ .

**perfectly-plastic.** An idealization of plastic behavior that exhibits no strain hardening.

**perforating.** The punching of many holes, usually identical and arranged in a regular pattern, in a sheet, workpiece blank, or previously formed part. The holes are usually round but may be any shape. The operation is also called multiple punching. See also *piercing*.

**permanent set.** The deformation or strain remaining in a previously stressed body after release of the load.

**persistent anticlastic curvature.** *Anticlastic curvature* that remains after a bent sheet or beam is unloaded.

**physical modeling.** A subscale laboratory technique based on the principles of similarity used to study the effect of die design, material properties, and so forth on metal flow, defect formation, and so on during forging, extrusion, and other forming processes. The technique typically employs inexpensive die and workpiece materials. See also *visio-plasticity*.

**pickle patch.** Localized area of tightly adhering surface oxide that results from incomplete removal of hot mill scale during pickling.

**pickle stain.** Discoloration of metal after oxide removal during pickling resulting from improper passivation of the sheet surface.

**pickup.** Small particles of oxidized metal adhering to the surface of a *mill product*.

**piercing.** The general term for cutting (shearing or punching) openings, such as holes and slots, in sheet material, plate, or parts. This operation is similar to *blanking*; the difference is that the slug or piece produced by piercing is scrap, while the blank produced by blanking is the useful part.

**pin and bushing test.** A test in which an oversized pin is driven by a hydraulic piston into a bushing. The bushing is expanded, causing an increase in pressure at the interface. The change in outside diameter of the bushing at a given pressing force is related to the coefficient of friction.

**pinchers.** Surface defects having the appearance of ripples or of elongated areas of variable surface texture extending at an acute angle to the sheet rolling direction and often branching. Pinchers are usually caused by poor hot rolled strip shape or improper drafting or incorrect crown on the cold reduction mill. They are sometimes referred to as feather pattern.

**pinch point.** Any point other than the point of operation at which it is possible for a part of a press operator's body to be caught between the moving parts of a press or auxiliary equipment, between moving and stationary parts of a press or auxiliary equipment, or between the

material and a moving part or parts of the press or auxiliary equipment.

**pinch trimming.** The trimming of the edge of a tubular part or shell by pushing or pinching the flange or lip over the cutting edge of a stationary punch or over the cutting edge of a draw punch.

**pinning.** The retardation or complete cessation of grain growth during annealing or deformation by second-phase particles acting on grain boundaries.

**Piobert lines.** See *Lüders lines*.

**pit.** A small, clean depression in a sheet surface caused by the rolling-in of foreign particles such as sand, steel, and so on that subsequently fall out.

**planar anisotropy.** A term indicating variation in one or more physical or mechanical properties with direction in the plane of the sheet. The planar variation in plastic-strain ratio is commonly designated as  $\Delta r$ , given by:  $\Delta r = (r_0 + r_{90} - 2r_{45})/2$ . The earing tendency of a sheet is related to  $\Delta r$ . As  $\Delta r$  increases, so the tendency to form ears increases.

**plane strain.** Deformation in which the normal and shear components associated with one of the three coordinate directions are equal to zero. Bulk forming operations that approximate plane-strain conditions include sheet rolling and sheet drawing.

**plane stress.** Stress state in which the normal and shear components of stress associated with one of the three coordinate directions are equal to zero. Most sheet-forming operations are performed under conditions approximating plane stress.

**planishing.** Smoothing a metal surface by rolling, forging, or hammering; usually the last pass or passes of a shaping operation.

**plastic anisotropy factor or plastic anisotropy ratio.** See *plastic-strain ratio*.

**plastic deformation.** The permanent (inelastic) distortion of metals under applied stresses that strain the material beyond its *elastic limit*. The ability of metals to flow in a plastic manner without fracture is the fundamental basis for all metal-forming processes.

**plastic flow.** The phenomenon that takes place when metals or other substances are stretched or compressed permanently without rupture.

**plastic instability.** The deformation stage during which plastic flow is nonuniform and necking occurs.

**plasticity.** The ability of a metal to undergo permanent deformation without rupture.

**plastic strain.** The part of the total strain attributable to plastic, or irreversible, deformation. For simple elastic-plastic laws, it is the remainder when the elastic strains are removed from the total strains.

**plastic-strain ratio (*r*-value).** A measure of plastic anisotropy defined by the ratio of the true plastic width strain ( $\epsilon_w$ ) to the true plastic thickness strain ( $\epsilon_t$ ) in a tensile test. For large strains, the total strains are used to approximate the plastic strains. The average plastic-strain ratio,  $\bar{r}$  or  $r_m$ , is determined from

tensile samples taken in at least three directions from the sheet rolling direction, usually at 0, 45, and 90°. A formability parameter that relates to drawing, it is also known as the plastic anisotropy factor. A high *r*-value often correlates with good deep-drawing properties.

**plate.** See *sheet*.

**platen.** The sliding member, slide, or ram of a press.

**plowing (ploughing).** Plastic deformation of the surface of the softer component of a friction pair.

**plug.** (1) A rod or mandrel over which a pierced tube is forced. (2) A rod or mandrel that fills a tube as it is drawn through a die. (3) A punch or mandrel over which a cup is drawn. (4) A protruding portion of a die impression for forming a corresponding recess in the forging. (5) A false bottom in a die.

**point lattice.** A set of points in space located so that each point has identical surroundings. There are 14 ways of so arranging points in space, corresponding to the 14 *Bravais lattices*.

**point of operation.** The area of a press where material is actually positioned and work is performed during any process such as shearing, punching, forming, or assembling.

**Poisson contraction.** The transverse compressive strains that usually occur when a longitudinal extension is applied.

**Poisson's ratio.** The ratio of transverse elastic strain to longitudinal elastic strain experienced in a tensile test. Its use assumes isotropic behavior such that the transverse strains are equal for corresponding axial strain resulting from uniformly distributed axial stress below the *proportional limit* of the material in a tensile test.

**pole figure.** Description of crystallographic texture based on a stereographic-projection representation of the times-random probability of finding a specific crystallographic pole with a specific orientation relative to sample reference directions. For axisymmetric components, the sample reference directions are usually the axis and two radial directions; for a sheet material, the rolling, transverse, and sheet-normal directions are used. Because pole figures provide information only with regard to the orientation of one crystallographic pole, several pole figures or an orientation-distribution function (derivable from pole-figure measurements) are needed to fully describe crystallographic texture. See also *orientation-distribution function (ODF)*.

**polycrystalline aggregate.** The collection of grains/crystals that form a metallic material.

**polygonization.** A recovery-type process during the annealing of a worked material in which excess dislocations of a given sign rearrange themselves into low-energy, low-angle tilt boundaries.

**porosity.** Voids or pores within the workpiece; porosity is especially pertinent to powder forging.

**postforming operation.** Any treatment after the part has been formed, such as annealing, trimming, finishing, and so on.

**powder forging.** The plastic deformation of a powder metallurgy *compact* or *preform* into a fully dense finished shape by using compressive force; usually done hot and within closed dies.

**powder metallurgy.** A processing route consisting of the manufacture and subsequent consolidation of particulate (powder) materials to create shaped objects.

**power-driven hammer.** A forging hammer with a steam or air cylinder for raising the ram and augmenting its downward blow.

**power-law hardening.** A particularly simple form of strain hardening described by the equation  $\sigma = Ke^n$ , where  $\sigma$  is the true stress,  $\epsilon$  is the true strain,  $K$  is called the *strength coefficient*, and the value  $n$  is a constant called the *strain-hardening exponent* or strain-hardening power. Also called *Hollomon hardening*, after J.H. Hollomon.

**precision forging.** A forging produced to closer tolerances than normally considered standard by the industry.

**preferred orientation.** Nonrandom distribution of the crystallographic orientations of the grains comprising a polycrystalline aggregate.

**preform.** (1) The forging operation in which stock is preformed or shaped to a predetermined size and contour prior to subsequent die-forging operations. When a preform operation is required, it will precede a forging operation and will be performed in conjunction with the forging operation and in the same heat. (2) The initially pressed powder metallurgy *compact* to be subjected to *repressing*.

**prelubed sheet.** A sheet or coil that has had a lubricant applied during mill processing to serve as a forming lubricant in the fabrication plant.

**presence-sensing device.** A device designed, constructed, and arranged to create a sensing field or area and to deactivate the clutch control of a press when an operator's hand or any other body part is within such field or area.

**press.** A machine tool with a stationary bed and a slide or ram that has reciprocating motion at right angles to the bed surface; the slide is guided in the frame of the machine.

**press brake.** An open-frame single-action press used to bend, blank, corrugate, curl, notch, perforate, pierce, or punch sheet metal or plate.

**press-brake bend test.** A bend test for sheet metal in which one side of the specimen is clamped and a press brake is used to bend the metal over its designed radius and with proper clearance.

**press capacity.** The rated force a press is designed to exert at a predetermined distance above the bottom of the stroke of the slide.

**press component or mechanical power press component.** The basic press (component) of the mechanical power press machine; that

portion devoid of the tooling component, the safe-guarding component(s), and auxiliary feeding components. The press component is usually a multifunctional piece of equipment that is adaptable to a limitless combination of circumstances, depending on the other components incorporated with it.

**press forging.** The forging of metal between dies by mechanical or hydraulic pressure; usually accomplished with a single work stroke of the press for each die station.

**press forming.** Any sheet-metal forming operation performed with tooling by means of a mechanical or hydraulic press.

**pressing.** The product or process of shallow drawing sheet or plate.

**press load.** The amount of force exerted in a given forging or forming operation.

**press slide.** See *slide*.

**press speed.** Ram velocity (hydraulic/screw presses) or the number of strokes of the press slide in a unit of time (mechanical press). Generally expressed as strokes per minute (spm) or inches per minute (ipm).

**pressure pad.** A plate (flat or profiled) actuated by mechanical or fluid force to control metal movement and/or flow.

**pressure plate.** A plate located beneath the bolster that acts against the resistance of a group of cylinders mounted to the pressure plate to provide uniform pressure throughout the press stroke when the press is symmetrically loaded.

**principal strain.** The normal strain on any of three mutually perpendicular planes on which no shear strains are present.

**principal strain direction.** The direction perpendicular to any of the three mutually perpendicular planes on which no shear strains are present.

**principal stress.** One of the three normal stresses in the coordinate system in which all of the shear stresses are equal to zero.

**prior particle boundary.** An apparent boundary between the pre-existing powder metal particles that is still evident within the microstructure of consolidated powder metallurgy products because of the presence of carbide or other phases that form at these boundaries.

**processing map.** A map of strain rate versus temperature that delineates the regions that should be avoided in processing to prevent the formation of poor microstructures or voids or cracks. These maps are generally created by the dynamic material modeling method or by mapping extensive results of processing experience.

**process modeling.** Computer simulation of deformation, heat treating, and machining processes for the purpose of improving process yield and material properties.

**profile (contour) rolling.** In *ring rolling*, a process used to produce seamless rolled rings with a predesigned shape on the outside or the inside diameter, requiring less volume of material and less machining to produce finished parts.

**progression.** The constant dimension between adjacent stations in a progressive die.

**progressive.** A planned sequence to accomplish press-working operations consecutively.

**progressive die.** A die planned to accomplish a sequence of operations as the strip or sheet or material is advanced from station to station, manually or mechanically.

**progressive forming.** Sequential forming at consecutive stations with a single die or separate dies.

**progressive ironing.** A cold forming process in which a part is shaped by a succession of ironing operations. The successive operations may occur in one or a series of dies.

**projection welding.** Electrical resistance welding in which the welds are localized at embossments or other raised portions of the sheet surface.

**proof.** Any reproduction of a die impression in any material; often a lead or plaster cast. See also *die proof (cast)*.

**proof load.** A predetermined load, generally some multiple of the service load, to which a specimen or structure is submitted before acceptance for use.

**proof stress.** (1) The stress that will cause a specified small permanent set in a material. (2) A specified stress to be applied to a member or structure to indicate its ability to withstand service loads.

**proportional limit.** The stress at which deviation from straight-line proportionality between stress and strain is observed. The value depends intimately on the resolution of measured stress and strain. See also *elastic limit* and *Hooke's law*.

**pull-out device.** A mechanism attached to an operator's hands and connected to the upper die or *slide* of a press that is intended, when properly adjusted, to withdraw the operator's hands as the dies close, if the operator's hands are inadvertently within the point of operation.

**punch.** (1) The male part of a die—as distinguished from the female part, which is called the die. The punch is usually the upper member of the complete die assembly and is mounted on the *slide* or in a *die set* for alignment (except in the inverted die). (2) In double-action draw dies, the punch is the inner portion of the upper die, which is mounted on the plunger (inner slide) and does the drawing. (3) The act of piercing or punching a hole. Also referred to as *punching*.

**punching.** The die shearing of a closed contour in which the sheared-out sheet-metal part is scrap.

**punch-load/punch travel diagram.** A diagram showing the relationship between the main ram (punch) load of a press and the distance the punch has traveled during metal forming.

**punch nose radius.** The shape of the punch end, contacting the material being formed to allow proper material flow or movement.

**punch press.** (1) In general, any mechanical press. (2) In particular, an endwheel gap-frame press with a fixed bed, used in piercing.

**punch retainer.** The detail or component of a die that holds the punch in working position and also permits easy removal.

**punch section.** A section of the punch used in cutting, forming, or flanging operations that is fastened to outer sections to make up the complete punch working edge.

**punch slide.** The main reciprocating member of a press. See *slide*.

## Q

**quadratic element.** A finite element that assumes that the pattern of displacements inside the element varies quadratically with position inside the element.

**quarter hard.** A temper of nonferrous alloys and some ferrous alloys characterized by tensile strength approximately midway between that of dead-soft and half-hard tempers.

**quench aging.** Hardening by precipitation that results after the rapid cooling from solid solution to a temperature below which the elements of a second phase become supersaturated. Precipitation occurs after the application of higher temperatures and/or times and causes increases in yield strength, tensile strength, and hardness.

## R

**rabbit ear.** Recess in the corner of a metal-forming die to allow for wrinkling or folding of the blank.

**radial draw forming.** The forming of sheet metals by the simultaneous application of tangential stretch and radial compression forces. The operation is done gradually by tangential contact with the die member. This type of forming is characterized by very close dimensional control.

**radial forging.** A process using two or more moving anvils or dies for producing shafts with constant or varying diameters along their length or tubes with internal or external variations in diameter. Often incorrectly referred to as *rotary forging*.

**radial rolling force.** The action produced by the horizontal pressing force of the rolling mandrel acting against the ring and the main roll.

**radial roll (main roll, king roll).** The primary driven roll of the rolling mill for rolling rings in the radial pass. The roll is supported at both ends.

**radius.** To remove the sharp edge or corner of forging stock by means of a radius or form tool.

**ram.** The moving or falling part of a drop hammer or press to which one of the dies is attached; sometimes applied to the upper flat

die of a steam hammer. Also referred to as the *slide*.

**recoil line.** See *impact line*.

**re-coil lines.** Blemishes in the form of repetitive lines of variable spacing extending transverse to the length of the coiled sheet and caused by coil breaks or leveler breaks.

**recovery.** Process occurring during annealing following cold or hot working of metals in which defects such as dislocations are eliminated or rearranged by way of mechanisms such as dipole annihilation, the formation of subgrains, and subgrain growth. Recovery usually leads to a reduction in stored energy, softening, reduction or elimination of residual stresses, and, in some instances, changes in physical properties. Recovery may also serve as a precursor to static recrystallization at sufficient levels of prior cold or hot work. See also *dynamic recovery*.

**recrystallization.** A process of nucleation and growth of new strain-free grains or crystals in a material. This process occurs upon heating above the recrystallization temperature (approximately 40% of the absolute melting temperature) during/after hot working or during annealing after cold working. Recrystallization can be dynamic (occurring during straining), static (occurring following deformation, typically during heat treatment), or metadynamic (occurring immediately after deformation due to the presence of recrystallization nuclei formed during deformation).

**recrystallization texture.** Crystallographic texture formed during static or dynamic recrystallization. The specific texture components that are formed are dependent on the nature of the stored work driving recrystallization and the nucleation and growth mechanisms that underlie recrystallization.

**redrawing.** The second and successive deep-drawing operations in which cuplike shells are deepened and reduced in cross-sectional dimensions.

**reduction.** (1) In cupping and deep drawing, a measure of the percentage of decrease from blank diameter to cup diameter, or of the diameter reduction in redrawing. (2) In forging, extrusion, rolling, and drawing, either the ratio of the original to the final cross-sectional area or the percentage of decrease in cross-sectional area.

**reduction in area.** The difference between the original cross-sectional area and the smallest area at the point of rupture in a tensile test; usually stated as a percentage of the original area.

**redundant work.** Energy in addition to that required for uniform flow expended during processing due to inhomogeneous deformation.

**relative density.** Ratio of density to pore-free density.

**relief.** Clearance obtained by removing material, either behind or beyond the cutting edge of a punch or die.

**repressing.** The application of pressure to a sintered compact; usually done to improve a physical or mechanical property or for dimensional accuracy.

**rerolling quality.** Rolled billets from which the surface defects have not been removed or completely removed.

**reset.** The realigning or adjusting of dies or tools during a production run; not to be confused with the operation setup that occurs before a production run.

**residual stress.** Stresses that remain in an unloaded body as a result of, for example, nonuniform plastic deformation or heating and cooling.

**restriking.** (1) The striking of a trimmed but slightly misaligned or otherwise faulty forging with one or more blows to improve alignment, improve surface condition, maintain close tolerances, increase hardness, or effect other improvements. (2) A sizing operation in which coining or stretching is used to correct or alter profiles and to counteract distortion. (3) A salvage operation following a primary forging operation in which the parts involved are rehit in the same forging die in which the pieces were last forged.

**return die.** A type of die, particularly cutting, in which the slug or blank is returned to the die surface for removal.

**reverse drawing.** *Redrawing* of a sheet-metal part in a direction opposite to that of the original drawing.

**reverse flange.** A sheet-metal flange made by shrinking, as opposed to one formed by stretching.

**reverse redrawing.** An operation after the first drawing operation in which the part is turned inside out by inverting and redrawing, usually in another die, to a smaller diameter.

**rib.** (1) A long V-shaped or radiused indentation used to strengthen large sheet-metal panels. (2) A long, usually thin protuberance used to provide flexural strength to a forging (as in a rib-web forging).

**rigid.** An idealized material behavior where the elastic constants are infinite such that no elastic straining occurs.

**ring compression test.** A workability test that uses the expansion or contraction of the hole in a thin compressed ring to measure the frictional conditions. The test can also be used to determine the flow stress.

**ring rolling.** The process of shaping weldless rings from pierced disks or shaping thick-wall ring-shaped blanks between rolls that control wall thickness, ring diameter, height, and contour.

**rocker arm press.** A press in which the force to perform work is transmitted from the driving system to the driven platen or ram by a rocker arm through a fulcrum.

**rod.** A solid round section 9.5 mm ( $\frac{3}{8}$  in.) or greater in diameter whose length is great in relation to its diameter.

**roll.** Tooling used in the rolling process to deform material stock.

**roll bending.** The curving of sheets, bars, and sections by means of rolls.

**rolled-in dirt.** Extraneous material rolled into the surface of sheet metal.

**rolled-in scale.** Localized areas of heavy oxide not removed by the hot mill descaling sprays and rolled out to elongated streaks during further processing.

**roller leveler breaks.** Obvious transverse breaks on sheet metal usually approximately 3 to 6 mm ( $1/8$  to  $1/4$  in.) apart that are caused by the sheet fluting during *roller leveling*. These will not be removed by stretching.

**roller leveling.** *Leveling* by passing flat sheet-metal stock through a machine having a series of small-diameter staggered rolls that are adjusted to produce repeated reverse bending.

**roll feed.** A mechanism for feeding strip or sheet stock to a press or other machine. The stock passes between two revolving rolls mounted one above the other, which feed it under the dies a predetermined length at each stroke of the press. Two common types of drive are the oscillating lever type and the rack-and-pinion type. The single roll feed may be used to either push or pull the stock to or from the press. The double roll feed is commonly used with wider presses (left to right) or in other cases where a single roll feed is impractical.

**roll flattening.** The flattening of sheets that have been rolled in packs by passing them separately through a two-high cold mill with virtually no deformation. Not to be confused with *roller leveling*.

**roll forging.** A process of shaping stock between two driven rolls that rotate in opposite directions and have one or more matching sets of grooves in the rolls; used to produce finished parts or preforms for subsequent forging operations.

**roll former.** A device with three or more rolls positioned to progressively plastically form sheet or strip metal into curved or linear shapes.

**roll forming.** Metal forming through the use of power-driven rolls whose contour determines the shape of the product; sometimes used to denote power *spinning*.

**rolling.** The reduction of the cross-sectional area of metal stock, or the general shaping of metal products, through the use of rotating rolls.

**rolling mandrel.** In ring rolling, a vertical roll of sufficient diameter to accept various sizes of ring blanks and to exert rolling force on an axis parallel to the main roll.

**rolling mills.** Machines used to decrease the cross-sectional area of metal stock and to produce certain desired shapes as the metal passes between rotating rolls mounted in a framework comprising a basic unit called a *stand*. Cylindrical rolls produce flat shapes; grooved rolls produce rounds, squares, and structural shapes. See also *four-high mill*, *Senzimir mill*, and *two-high mill*.

**roll mark.** A mark in light relief on the sheet surface produced by an indentation in the cold reduction mill work roll surface.

**roll pick-up.** Repetitive marks or indentations in sheets caused by extraneous material that has adhered to a work roll in the cold reduction mill or temper mill.

**roll straightening.** The straightening of metal stock of various shapes by passing it through a series of staggered rolls (the rolls usually being in horizontal and vertical planes) or by reeling in two-roll straightening machines.

**roll threading.** The production of threads by rolling the piece between two grooved die plates, one of which is in motion, or between rotating grooved circular rolls.

**roping.** A surface defect consisting of a series of generally parallel markings or ripples on areas of rolled formed sheet parts that have undergone substantial strain. The ripples are always parallel to rolling direction.

**rotary forging.** A process in which the work-piece is pressed between a flat anvil and a swiveling (rocking) die with a conical working face; the platens move toward each other during forging. Also called orbital forging. Compare with *radial forging*.

**rotary shear.** A sheet-metal cutting machine with two rotating-disk cutters mounted on parallel shafts driven in unison.

**rotary swager.** A swaging machine consisting of a power-driven ring that revolves at high speed, causing rollers to engage cam surfaces and force the dies to deliver hammerlike blows on the work at high frequency. Both straight and tapered sections can be produced.

**rotary swaging.** A *bulk forming* process for reducing the cross-sectional area or otherwise changing the shape of bars, tubes, or wires by repeated radial blows with one or more pairs of opposed dies.

**rough blank.** A blank for a forming or drawing operation, usually of irregular outline, with necessary stock allowance for process metal, which is trimmed after forming or drawing to the desired size.

**roughing stand.** The first stand (or several stands) of rolls through which a reheated billet or slab passes in front of the finishing stands. See also *rolling mills* and *stand*.

**roughness cut-off level.** Terms used in the measurement of surface roughness. (1) Width cut-off: the greatest spacing of repetitive surface irregularities used in the measurement of roughness, usually 0.75 mm (0.030 in.). (2) Height cut-off: the minimum surface irregularity in peak count determinations, usually 1.3  $\mu$ m (50  $\mu$ in.).

**roughness height.** The average height of surface irregularities with reference to a mean or nominal surface as determined by height and width cut-offs. It may be expressed as the deviation from the nominal surface, as arithmetic average, or as root mean square.

**$R/t$  ratio.** A normalized dimensionless expression of the radius of curvature after bending ( $R$ ) to the thickness of the section,  $t$ . Smaller

numbers refer to more severe bending, with  $R/t$  of approximately 5 to 6 usually being considered the lower limit for application of simple shell theories of bending.

**rubber forming.** A sheet-metal forming process in which rubber is used as a functional die part.

**rubber-pad forming.** A sheet-metal forming operation for shallow parts in which a confined, pliable rubber pad attached to the press slide (ram) is forced by hydraulic pressure to become a mating die for a punch or group of punches placed on the press bed or baseplate. Developed in the aircraft industry for the limited production of a large number of diversified parts, the process is limited to the forming of relatively shallow parts, normally not exceeding 40 mm (1.5 in.) deep. Also known as the *Guerin process*. Variations of the Guerin process include the *Marforming process*, the *fluid-cell process*, and *fluid forming*.

**run.** The quantity produced in one setup.

**$r$ -value.** See *plastic-strain ratio*.

## S

**saddening.** The process of lightly working an ingot in the initial forging operation to break up and refine the coarse, as-cast structure at the surface.

**scale pattern.** A transverse surface pattern on cold rolled sheet caused by intermittent removal of the scale in the scale-breaker operation prior to pickling. The result is a pattern of overpickled areas that are not eliminated in cold reduction.

**Schmid factor.** In a uniaxial tension test, the geometric factor that corresponds to the product of the cosine of the angle between the tension axis and the slip-plane normal and the cosine of the angle between the tension axis and the slip direction. Often denoted as  $m$ .

**Schmid's law.** Criterion that slip in metallic crystals is controlled by a critical resolved shear stress that depends on specific material, strain rate, and test temperature but is independent of the stress normal to the slip plane.

**scoring.** (1) The marring or scratching of any formed part by metal pickup on the punch or die. (2) The reduction in thickness of a material along a line to weaken it intentionally along that line.

**scrap mark.** A type of roll mark caused by rolling over ragged coiled edges or coil ends. See also *roll mark*.

**scratches.** Lines generally caused by sliding of the sheet surface over sharp edges of processing equipment or over other sheets.

**scratch resistance.** The ability of a material to resist scratching. It is a function of the material hardness, although the lubricity of the surface will also play a part.

**screw dislocation.** A line imperfection that corresponds to the axis of a spiral structure in a crystal and is characterized by a distortion

- joining normally parallel lines together to form a continuous helical ramp (with a pitch of one interplanar distance) winding about the dislocation.
- screw press.** A high-speed press in which the ram is activated by a large screw assembly powered by a drive mechanism.
- scuffing.** Localized damage caused by the occurrence of solid-phase welding between sliding surfaces. No local surface melting occurs. See also *galling* and *scoring*.
- seam.** A surface defect appearing as thin lines in the rolling direction of sheet metals due to voids elongated during rolling.
- seaming.** The process of joining sheet-metal parts by interlocking bends.
- secant modulus.** The slope of the secant drawn from the origin to any specified point on the stress-strain curve. See also *modulus of elasticity*.
- secondary recrystallization.** See *abnormal grain growth*.
- secondary tensile stress.** Tensile stress that develops during a bulk deformation process conducted under nominally compressive loading due to nonuniform metal flow resulting from geometry, friction, or die-chilling effects. Secondary tensile stresses are most prevalent in open-die forging operations.
- secondary sheet.** A shearing action that occurs between soft work metal and a cutting edge as a result of insufficient clearance.
- segment die.** Same as *split die*.
- segregation.** A nonuniform distribution of alloying elements, impurities, or micro-phases.
- seizure.** The stopping of relative motion between two bodies as the result of severe interfacial friction. Seizure may be accompanied by gross surface welding.
- semifinisher.** An impression in a series of forging dies that only approximates the finish dimensions of the forging. Semifinishers are often used to extend die life or the finishing impression, to ensure proper control of grain flow during forging, and to assist in obtaining desired tolerances.
- seminotching.** A process similar to notching except that the cutting operation is a partial one only, permitting the cut shape to remain with the blank or part. Thus, by a series of seminotching actions from coil stock, the workpiece is still retained in the strip skeleton.
- Sendzimir mill.** A type of *cluster mill* with small-diameter work rolls and larger-diameter backup rolls, backed up by bearings on a shaft mounted eccentrically so that it can be rotated to increase the pressure between the bearing and the backup rolls. Used to roll precision and very thin strip. Note: Sendzimir mills roll strip, not sheets.
- set.** The shape remaining in a stamped or press-formed part after the punch force is removed. See also *permanent set*.
- severe plastic deformation.** Processes of plastic deformation with accumulated natural logarithmic strains more than 4 that are usually used to change material structure and properties.
- shank.** The portion of a die or tool by which it is held in position in a forging unit or press.
- shape distortion.** A dimensional change due to warping or bending resulting mainly from thermal treatment.
- shape fixability.** The ability of a material to retain the shape given to it by a forming operation.
- shaving.** Backflow of the clad or sleeve material during hydrostatic coextrusion.
- shear.** (1) A machine or tool for cutting metal and other material by the closing motion of two sharp, closely adjoining edges, for example, squaring shear and circular shear. (2) An inclination between two cutting edges, such as between two straight knife blades or between the punch cutting edge and the die cutting edge, so that a reduced area will be cut each time. This lessens the necessary force but increases the required length of the working stroke. This method is referred to as angular shear. (3) The act of cutting by shearing dies or blades, as in a squaring shear. (4) The type of force that causes or tends to cause two contiguous parts of the same body to slide relative to each other in a direction parallel to their plane of contact.
- shear band.** Region of highly localized shear deformation developed during bulk forming (and sometimes during sheet forming) as a result of material properties (such as a high flow-softening rate and low rate sensitivity of the flow stress), metal flow geometry, friction, chilling, and so on.
- shear burr.** A raised edge resulting from metal flow induced by blanking, cutting, or punching.
- shearing.** A cutting operation in which the work metal is placed between a stationary lower blade and movable upper blade and severed by bringing the blades together. Cutting occurs by a combination of metal shearing and actual fracture of the metal.
- shear strength.** The maximum shear stress a material can sustain. Shear strength is calculated from the maximum load during a shear or torsion test and is based on the original dimensions of the cross section of the specimen.
- shear stress.** (1) A stress that exists when parallel planes in metal crystals slide across each other. (2) The stress component tangential to the plane on which the forces act.
- sheet.** Any material or piece of substantially uniform thickness and of considerable length and width as compared to its thickness. With regard to metal, such pieces under 6.5 mm (1/4 in.) thick are called sheets, and those 6.5 mm (1/4 in.) thick and over are called plates. Occasionally, the limiting thickness for steel to be designated as sheet steel is No. 10 Manufacturer's Standard Gage for sheet steel, which is 3.42 mm (0.1345 in.) thick.
- sheet bar.** Workpiece, usually with a rectangular cross section, typically used in a batch (hand mill) sheet-rolling process.
- sheet forming.** The plastic deformation of a piece of sheet metal by tensile loads into a three-dimensional shape, often without significant changes in sheet thickness or surface characteristics. Compare with *bulk forming*.
- sheet tension.** The tensile force tending to extend a sheet in the sheet plane. It is expressed in units of force and may be computed from the stress distribution through the thickness by integrating the differential force through the section.
- sheet tension stress.** A stresslike quantity obtained by dividing the sheet tension by the cross-sectional area on which the sheet tension force operates.
- shell element.** A kind of finite element that takes advantage of one dimension being much smaller than the other two by reducing the small dimension to zero while adopting an approximate relationship between location in the sheet or beam thickness and strain, usually linear. If no bending strains are allowed, that is, the strains are uniform through the sheet thickness, a shell element becomes a membrane element. Also called thin-shell element.
- shell four-ball test.** A lubricant test in which three balls are clamped in contact as in an equilateral triangle. The fourth ball is held in a rotating chuck and touches each of the stationary balls. Load is applied through a lever arm system that pushes the stationary balls upward against the rotating ball.
- shim.** A thin piece of material used between two surfaces to obtain a proper fit, adjustment, or alignment.
- shrinkage.** The contraction of metal during cooling after hot forging. Die impressions are made oversized according to precise shrinkage scales to allow the forgings to shrink to design dimensions and tolerances.
- shrink flanging.** The reduction of the length of the free edge after the flanging process.
- shut height.** For a press, the distance from the top of the bed to the bottom of the slide with the stroke down and adjustment up. In general, it is the maximum die height that can be accommodated for normal operation, taking the *bolster* plate into consideration.
- shuttle die.** A multiple-station die in which the separated workpieces are fed from station to station by bars that are positioned in the die proper. Also known as a transfer die.
- side housings.** Uprights or spacers extending from front to back and used to separate the crown and the bed on a hydraulic press.
- side-plate press.** A type of hydraulic press in which the crown and bed are separated by steel plate strain members, one on each side. The side plates are fastened to the crown and head.
- sidepressing.** A deformation process in which a cylinder is laid on its side and deformed in

compression. It is a good test to evaluate the tendency for fracture at the center of a billet, or for evaluating the tendency to form shear bands.

**side thrust.** The lateral force exerted between the dies by reaction of a forged piece on the die impressions.

**side-wall curl.** The curving of the region of sheet drawn into the die cavity in a *channel forming* operation, when the forming forces are removed and *springback* occurs.

**single-action hydraulic press.** One equipped with one moving slide member. A single-action press may have a *cushion* built into the bed.

**single-action press.** A press having one ram or slide. Also refers to a draw die that does not have a blankholder.

**single-stand mill.** A rolling mill designed such that the product contacts only two rolls at a given moment. Contrast with *tandem mill*.

**sinking.** The operation of machining the impression of a desired forging into die blocks.

**sintering.** The densification and bonding of adjacent particles in a powder mass or compact by heating to a temperature below the melting point of the main constituent.

**sizing.** (1) Secondary forming or squeezing operations needed to square up, set down, flatten, or otherwise correct surfaces to produce specified dimensions and tolerances. See *restriking*. (2) Some burnishing, broaching, drawing, and shaving operations are also called sizing. (3) A finishing operation for correcting ovality in tubing. (4) Final pressing of a sintered powder metallurgy part.

**skin lamination.** A subsurface separation that can result in surface rupture during forming.

**slab.** Flat-shaped semifinished rolled metal stock section with a width not less than 250 mm (10 in.) and a cross-sectional area not less than 105 cm<sup>2</sup> (16 in.<sup>2</sup>).

**slabbing.** The hot working of an ingot to a flat rectangular shape.

**sleeve.** Outer layer of a coextruded or codrawn product. See also *clad*.

**slide.** The main reciprocating member of a press, guided in the press frame, to which the punch or upper die is fastened; sometimes called the *ram*. The inner slide of a double-action press is called the plunger or punchholder slide; the outer slide is called the blankholder slide. The third slide of a triple-action press is called the lower slide, and the slide of a hydraulic press is often called the platen.

**slide adjustment.** The distance that a press slide position can be altered to change the shut height of the die space. The adjustment can be made by hand or by power mechanism.

**sliding friction test—flat dies.** A test in which a sheet steel sample is placed between two flat, hardened die faces and pulled through the dies under conditions that permit recording of the load applied to the dies and the force required to pull the strip.

**sliding friction test—wedge dies.** Similar to the flat-die test assembly except that one or both of the flat dies has a wedge configuration to confine the edges of the specimen. This permits development of unit loadings in excess of compressive strength of the specimen, and cold reduction of drawn strip is readily accomplished.

**slip.** Crystallographic shear process associated with dislocation glide that underlies the large plastic deformation of crystalline metals and alloys. Slip is usually observed on close-packed planes along close-packed directions, in which case it is referred to as restricted slip. In body-centered cubic materials, such as alpha iron, slip occurs along any plane containing a close-packed direction and is referred to as pencil glide.

**slip-line field.** Graphical technique used to estimate the deformation and stresses involved in plane-strain metal-forming processes.

**slitting.** Cutting or shearing along single lines to cut strips from a sheet or to cut along lines of a given length or contour in a sheet or workpiece.

**sliver.** A surface defect consisting of an elongated thin layer of partially attached metal.

**slotting.** A stamping operation in which elongated or rectangular holes are cut in a blank or part.

**slug.** (1) The metal removed when punching a hole in a forging; also termed punchout. (2) The forging stock for one workpiece cut to length. See also *blank*.

**slugging.** A sheet-metal cutting operation in which the steel punch is set to enter the sheet metal the exact amount of penetration required to complete fracturing. Due to cold welding and springback of the sheet metal, the slug remains in the sheet despite the completion of fracture.

**smith forging.** See *hand forge (smith forge)*.

**smudge.** A dark-appearing surface contamination on annealed sheet generally resulting from cold-reduction oil residues or carbon deposited from annealing gas with an unfavorable CO/CO<sub>2</sub> ratio. Smudge may adversely affect painting or plating but may be beneficial in the prevention of galling.

**smut.** A contaminant consisting of fine, dark-colored particles on the surface of pickled sheet products. This usually results from heavy oxidation of the steel surface during hot rolling.

**snap through.** Shock in a die due to the sudden beginning and completion of fractures in cutting dies causing the compressed punch to elastically snap into tension.

**solid press.** A type of hydraulic press in which the crown and bed are separated by side members that are an integral part of the crown and bed.

**sow block.** A block of heat treated steel placed between the anvil of the hammer and the forging die to prevent undue wear to the anvil. Sow blocks are occasionally used to hold insert dies. Also called anvil cap.

**space lattice.** A set of equal and adjoining parallelepipeds formed by dividing space by three sets of parallel planes, the planes in any one set being equally spaced. There are seven ways of so dividing space, corresponding to the seven *crystal system* structures. The unit parallelepiped is usually chosen as the unit cell of the system. Due to geometrical considerations, atoms can only have one of 14 possible arrangements, known as *Bravais lattices*.

**spalling.** The removal of small pieces of metal from the working face of the die, usually as a result of severe heat checking. Spalling is most likely in hard materials with low ductility.

**spank.** A press operation used to reform parts that have already had their major contour formed or drawn in the conventional manner. The spank operation is often used where it is not possible to produce the final contour, such as sharp creases or corners, in a single forming operation. It is also used at the end of a production line where large sheet-metal parts have become distorted due to previous operations such as trimming, punching, forming, and flanging. Spanking is used to bring the panels back to the desired contour. See also *restriking*.

**special boundary.** A boundary between two grains whose crystallographic lattices have a certain fraction ( $1/N$ , in which  $N$  is an integer) of coincident lattice points. Such boundaries, denoted using the notation  $\Sigma N$ , may have low mobility and surface energy.

**specific heat.** Amount of heat required to change the temperature of one unit weight of a material by one degree.

**spheroidization.** Process of converting a lamellar, basketweave, or acicular second phase into an equiaxed morphology via deformation, annealing, or a combination of deformation followed by annealing.

**spinning.** The forming of a seamless hollow metal part by forcing a rotating blank to conform to a shaped mandrel that rotates concentrically with the blank. In the typical application, a flat-rolled metal blank is forced against the mandrel by a blunt, rounded tool; however, other stock (notably, welded or seamless tubing) can be formed. A roller is sometimes used as the working end of the tool.

**split die.** A die made of parts that can be separated for ready removal of the workpiece. Also known as segment die.

**springback.** The elastically driven, usually undesirable, change of shape that occurs after forming when the external forces are removed. It is often expressed as a change of curvature, that is, the original curvature less the final curvature, which is generally greater than 1. This effect can be compensated for by overbending or by a secondary operation of *restriking*.

**springback ratio.** The ratio of the radius of curvature after *springback* (that is, in the unloaded state) to the radius at the end of forming (while still loaded). The ratio is generally positive.

**springforward.** A *springback* compensation method characterized by a step in which the forces opposite of those that induce springback are applied to induce an opposite change of shape, with the objective of attaining a die shape that will produce a desired shape after springback.

**spring holddown.** A general term for a spring-actuated pressure plate that could be a stripper in a cutting die, a holddown plate in a square shear, or a pad in a bending die.

**stacking-fault energy (SFE).** The energy associated with the planar fault formed by dissociated dislocations in crystalline materials. Low-SFE materials typically have wide stacking faults, and high-SFE materials very narrow or no stacking faults. The SFE affects a number of material properties, such as work-hardening rate and recrystallization. Materials with low SFE undergo rapid dislocation multiplication and hence show high work-hardening rates and relative ease of dynamic recrystallization because of the difficulty of dynamic recovery. Materials with high SFE energies usually exhibit low work-hardening rates because of the ease of dynamic recovery and are difficult to recrystallize.

**stamping.** A general term to denote all press-working. In a more specific sense, stamping is used to imprint letters, numerals, and trademarks in sheet metal, machined parts, forgings, and castings. A tool called a stamp, with the letter or number raised on its surface, is hammered or forced into the metal, leaving a depression on the surface in the form of the letter or number.

**stand.** A piece of rolling mill equipment containing one set of work rolls. In the usual sense, any pass of a cold or hot rolling mill. See also *rolling mills*.

**static friction.** The force tangential to the interface that is just sufficient to initiate relative motion between two bodies under load.

**steam hammer.** A type of drop hammer in which the ram is raised for each stroke by a double-action steam cylinder, and the energy delivered to the workpiece is supplied by the velocity and weight of the ram and attached upper die driven downward by steam pressure. The energy delivered during each stroke can be varied.

**sticker breaks.** Repetitive transverse lines, often curved, caused by localized welding of coil wraps during annealing and subsequent separation of these welded areas during an uncoiling operation. Also referred to as sticker marks.

**stiffness.** Resistance to elastic deformation.

**stock.** A general term used to refer to a supply of metal in any form or shape and also to an individual piece of metal that is formed, forged, or machined to make parts.

**stop.** A device for positioning stock or parts in a die.

**straightening.** A finishing operation for correcting misalignment in a forging or between various sections of a forging.

**straight-side press.** A box-shaped press having frame components of a bed, two uprights and a crown either welded together or clamped with tie rods.

**strain.** The unit of change in the size or shape of a body due to force, in reference to its original size or shape.

**strain aging.** The changes in ductility, hardness, yield point, and tensile strength that occur when a metal or alloy that has been cold worked is stored for some time. In steel, strain aging is characterized by a loss of ductility and a corresponding increase in hardness, yield point, and tensile strength.

**strain hardening.** An increase in hardness and strength caused by plastic deformation at temperatures below the recrystallization range. Also known as work hardening.

**strain-hardening coefficient.** See *strain-hardening exponent*.

**strain-hardening exponent.** For materials that closely obey a power-law relationship, the value  $n$  in the relationship  $\sigma = K\epsilon^n$ , where  $\sigma$  is the true stress,  $\epsilon$  is the true strain,  $K$  is called the *strength coefficient*, and  $n$  is a constant called the strain-hardening exponent or strain-hardening power. More generally, the slope of the logarithmic stress-strain curve, that is,  $d\ln\sigma/d\ln\epsilon$ , is called the incremental  $n$ -value or instantaneous  $n$ -value. For power-law materials,  $n$  is related to the ability of a sheet material to be stretched in tension. Also called the  $n$ -value and the work-hardening exponent.

**strain lines.** Surface defects in the form of shallow line-type depressions appearing in sheet metals after stretching the surface a few percent of unit area or length. See also *Lüders lines*.

**strain rate.** The time rate of deformation (strain) during a metal-forming process.

**strain-rate sensitivity.** The degree to which mechanical properties are affected by changes in deformation rate. Quantified by the slope of a log-log plot of flow stress (at fixed strain and temperature) versus strain rate. Also known as the  $m$ -value.

**strain-rod nuts.** Elements holding the bed or the crown to strain rods on a hydraulic press.

**strain rods.** The tension members joining the bed and the crown of a hydraulic press. Also called tie rods or columns.

**strain state.** (1) an expression of the ratios of the strain components without specifying their magnitudes. (2) An expression of the strain components in toto.

**strength.** The ability of a material to withstand an applied force.

**strength coefficient ( $K$ ).** The constant  $K$  in the power-law equation  $\sigma = K\epsilon^n$ .

**stress.** The intensity of the internally distributed forces or components of forces that resist a change in the volume or shape of a material that is or has been subjected to external forces. Stress is expressed in force per unit area. Stress can be normal (tension or compression) or shear.

**stress raisers.** Design features (such as sharp corners) or mechanical defects (such as notches) that act to intensify the stress at these locations.

**stress relaxation.** Drop in stress with time when material is maintained at a constant strain. The drop in stress is a result of plastic accommodation processes.

**stress state.** (1) An expression of the ratios of the stress components without specifying their magnitudes. (2) An expression of the stress components in toto.

**stress-strain curve.** See *stress-strain diagram*.

**stress-strain diagram.** A plot of stress and strain from a tension, compression, torsion, or other mechanical test. Values of stress are usually plotted vertically (ordinate, or  $y$ -axis) and values of strain horizontally (abscissa, or  $x$ -axis). Also known as stress-strain curve.

**stretchability.** The ability of a material to undergo stretch-type deformation.

**stretch-bend.** See *draw-bend*.

**stretcher leveling.** The leveling of a piece of sheet metal (that is, removing warp and distortion) by gripping it at both ends and subjecting it to a stress higher than its yield strength.

**stretcher straightening.** A process for straightening rod, tubing, and shapes by the application of tension at the ends of the stock. The products are elongated a definite amount to remove warpage.

**stretcher strains.** Elongated markings that appear on the surface of some sheet materials when deformed just past the yield point. These markings lie approximately parallel to the direction of maximum shear stress and are the result of localized yielding. See also *Lüders lines*.

**stretch flanging.** The stretching of the length of the free edge after the flanging process.

**stretch former.** (1) A machine used to perform *stretch forming* operations. (2) A device adaptable to a conventional press for accomplishing stretch forming.

**stretch forming.** The shaping of a sheet or part, usually of uniform cross section, by first applying suitable tension or stretch and then wrapping it around a die of the desired shape.

**stretching.** The mode of deformation in which a positive strain is generated on the sheet surface by the application of a tensile stress. In stretching, the flange of the flat blank is securely clamped. Deformation is restricted to the area initially within the die. The stretching limit is the onset of metal failure.

**striking surface.** Those areas on the faces of a set of dies that are designed to meet when the upper die and lower die are brought together. The striking surface helps protect impressions from impact shock and aids in maintaining longer die life.

**strip.** A flat-rolled metal product of some maximum thickness and width arbitrarily dependent on the type of metal; narrower than *sheet*.

**stripper.** A plate designed to remove, or strip, sheet-metal stock from the punching members

during the withdrawal cycle. Strippers are also used to guide small precision punches in close-tolerance dies, to guide scrap away from dies, and to assist in the cutting action. Strippers are made in two types: fixed and movable.

**stripper punch.** A punch that serves as the top or bottom of the die cavity and later moves farther into the die to eject the part or compact. See also *ejector rod* and *knockout*.

**stripping.** The removal of the metal strip from the punch after a cutting operation. Also a term referring to the removal of a part adhering to the punch on the upstroke after forming.

**strokes per minute.** The number of press-ram strokes or die closings in one minute.

**stroke (up or down).** The vertical movement of a ram during half of the cycle, from the full-open to the full-closed position or vice versa.

**subgrain.** Micron-sized volume bounded by well-defined dislocation walls. The misorientations across the walls are low angle in nature, that is,  $< 15^\circ$ .

**suppress die.** A die that is closed by the press ram but opened by springs or other means because the upper shoe is not attached to the ram.

**subso block (die holder).** A block used as an adapter in order to permit the use of forging dies that otherwise would not have sufficient height to be used in the particular unit or to permit the use of dies in a unit with different *shank* sizes.

**superplastic forming.** Forming using the superplasticity properties of material at elevated temperatures.

**superplastic forming and diffusion bonding.** The process of combining the diffusion bonding cycle into the superplastic forming.

**superplasticity.** The ability of certain metals to develop extremely high tensile elongations at elevated temperatures and under controlled rates of deformation. Materials that show high strain-rate sensitivity ( $m \geq 0.5$ ) at deformation temperatures often exhibit superplasticity. The phenomenon is often developed through a mechanism of grain-boundary sliding in very fine-grained, two-phase alloys.

**support plate.** A plate that supports a draw ring or draw plate. It also serves as a spacer.

**surface finish.** The classification of a surface in terms of roughness and peak density.

**surface hardness.** The hardness of that portion of the material very near the surface as measured by microhardness or superficial hardness testers.

**surface oxidation.** Development of an oxide film or layer on the surface of metals in oxidizing environments. Oxidation at high temperatures is occasionally referred to as sealing.

**surface roughness.** The fine irregularities in the surface texture that result from the production process. Considered as vertical deviations from the nominal or average plane of the surface.

**surface texture.** Repetitive or random deviations from the nominal surface that form the

pattern of the surface. Includes roughness, waviness, and flaws.

**swage.** (1) The operation of reducing or changing the cross-sectional area of stock by the fast impact of revolving dies. (2) The tapering of bar, rod, wire, or tubing by forging, hammering, or squeezing; reducing a section by progressively tapering lengthwise until the entire section attains the smaller dimension of the taper.

**sweep device.** A single or double arm (rod) attached to the upper die or slide of a press and intended to move the operator's hands to a safe position as the dies close, if the operator's hands are inadvertently within the point of operation.

**Swift cup test.** A simulative test in which circular blanks of various diameters are clamped in a die ring and deep drawn into a cup by a flat-bottomed cylindrical punch. The ratio of the largest blank diameter that can be drawn successfully to the cup diameter is known as the *limiting drawing ratio (LDR)* or *deformation limit*.

## T

**Taguchi method.** A technique for designing and performing experiments to investigate processes in which the output depends on many factors (e.g., material properties, process parameters) without having to tediously and uneconomically run the process using all possible combinations of values of those variables. By systematically choosing certain combinations of variables, it is possible to separate their individual effects.

**tailor-welded blank.** Blank for sheet forming typically consisting of steels of different thickness, grades/strengths, and sometimes coatings that are welded together prior to forming. Tailor-welded blanks are used to make finished parts with a desirable variation in properties such as strength, corrosion resistance, and so on.

**tandem die.** Same as *follow die*.

**tandem mill.** A rolling mill consisting of two or more stands arranged so that the metal being processed travels in a straight line from stand to stand. In continuous rolling, the various stands are synchronized so that the strip can be rolled in all stands simultaneously. Contrast with *single-stand mill*.

**tangent bending.** The forming of one or more identical bends having parallel axes by wiping sheet metal around one or more radius dies in a single operation. The sheet, which may have side flanges, is clamped against the radius die and then made to conform to the radius die by pressure from a rocker-plate die that moves along the periphery of the radius die. See also *wiper forming (wiping)*.

**tangent modulus.** The slope of the stress-strain curve at any specified stress or strain. See also *modulus of elasticity*.

**Taylor factor.** The ratio of the required stress for deformation under a specified strain state to the critical resolved shear stress for slip (or twinning) within the crystals comprising a *polycrystalline aggregate*. The determination of the Taylor factor assumes uniform and identical strain within each crystal in the aggregate and provides an upper bound on the required stresses. The Taylor factor averaged over all crystals in a polycrystalline aggregate ( $=\bar{M}$ ) provides an estimate of the effect of texture on strength.

**tearing.** Failure and localized separation of a sheet metal.

**temperature-compensated strain rate.** Parameter used to describe the interdependence of temperature and strain rate in the description of thermally activated (diffusion-like) deformation processes. It is defined as:

$$\dot{\epsilon} \exp(Q/RT),$$

in which  $\dot{\epsilon}$  denotes the strain rate,  $Q$  is an apparent activation energy characterizing the micromechanism of deformation,  $R$  is the gas constant, and  $T$  is the absolute temperature. Flow stress, dynamic recrystallization, and so on at various strain rates and temperatures are frequently interpreted in terms of the temperature-compensated strain rate. Also known as the *Zener-Hollomon parameter (Z)*.

**template (templet).** A gage or pattern made in a die department, usually from sheet steel; used to check dimensions on forgings and as an aid in sinking die impressions in order to correct dimensions.

**tensile ratio.** The ratio of the tensile strength to yield strength. It is the inverse of the yield ratio.

**tensile strength.** In tensile testing, the ratio of maximum load to original cross-sectional area. Also known as *ultimate strength*. Compare with *yield strength*.

**tension.** The force or load that produces elongation.

**texture.** The description of the relative probability of finding the crystals comprising a polycrystalline aggregate in various orientations.

**thermal conductivity.** A measure of the rate at which heat is transferred through a material.

**thermal-mechanical treatment.** See *thermo-mechanical processing (TMP)*.

**thermocouple.** A device for measuring temperature, consisting of two dissimilar metals that produce an electromotive force roughly proportional to the temperature difference between their hot and cold junction ends.

**thermomechanical processing (TMP).** A general term covering a variety of processes combining controlled thermal and deformation treatments to obtain synergistic effects, such as improvement in strength without loss of toughness. Same as *thermal-mechanical treatment*.

**thick-film lubrication.** A condition of lubrication in which the film thickness of the lubricant is appreciably greater than that required

to cover the surface asperities when subjected to the operating load. See also *thin-film lubrication*.

**thin-film lubrication.** A condition of lubrication in which the film thickness of the lubricant is such that the friction and wear between the surfaces is determined by the properties of the lubricant. See also *elastohydrodynamic lubrication* and *thick-film lubrication*.

**thin-shell element.** See *shell element*.

**three-point bending.** The bending of a piece of metal or a structural member in which the object is placed across two supports and force is applied between and in opposition to them. See also *V-bend die*.

**throw.** The distance from the centerline of the crankshaft or main shaft to the centerline of the crankpin or eccentric in crank or eccentric presses. Equal to one-half of the stroke. See also *crank press* and *eccentric press*.

**tilt boundary.** Grain boundary for which the crystal lattices of the grains on either side of the boundary are related by a rotation about an axis that lies in the plane of the boundary.

**toggle press.** A mechanical press in which the *slide* is actuated by one or more toggle links or mechanisms.

**tong hold.** The portion of a forging billet, usually on one end, that is gripped by the operator's tongs. It is removed from the part at the end of the forging operation. Common to drop hammer and press-type forging.

**tonnage.** The rated capacity of a press to exert force in closing the die. This rating is a short distance above the bottom of the stroke in mechanical presses.

**tooling marks.** Indications imparted to the surface of the forged part from dies containing surface imperfections or dies on which some repair work has been done. These marks are usually slight rises or depressions in the metal.

**top drive.** A press having the drive mechanism, including motor, flywheel, gears, shafts, and clutch, located in, just behind, or above the crown.

**torsion.** A twisting deformation of a solid or tubular body about an axis in which lines that were initially parallel to the axis become helices.

**torsional stress.** The *shear stress* on a transverse cross section resulting from a twisting action.

**total elongation.** The total amount of permanent extension of a testpiece broken in a tensile test; usually expressed as a percentage over a fixed gage length. See also *elongation, percent*.

**total strain.** Same as *strain* but modified to emphasize that it has not been decomposed into, for example, elastic and plastic strains.

**toughness.** The ability of a material to resist an impact load (high strain rate) or to deform under such a load in a ductile manner, absorbing a large amount of the impact energy and deforming plastically before fracturing. Such impact toughness is frequently evaluated with Charpy or Izod notched impact specimens. Impact toughness is measured in

terms of the energy absorbed during fracture. Fracture toughness is a measure of the ability of a material to withstand fracture in the presence of flaws under static or dynamic loading of various types (tensile, shear, etc.). An indicator of damage tolerance, fracture toughness is measured in terms of  $\text{MPa}\sqrt{\text{m}}$  or  $\text{ksi}\sqrt{\text{in.}}$

**transfer.** A system for moving stampings from press-to-press or station-to-station within a single large die using a grip-transfer-release motion. Activated by the press motion.

**trapped dies.** Dies designed with no allowance for flash. Typical configuration consists of a ring die with top and bottom punches.

**triaxiality.** The ratio of the hydrostatic (mean) stress to the flow (effective) stress. Triaxiality provides a measure of the tendency for cavities to grow during deformation processing.

**trimmer.** The dies used to remove the flash or excess stock from a forging.

**trimmer blade.** The portion of the trimmers through which a forging is pushed to shear off the flash.

**trimmer die.** The punch-press die used for trimming flash from a forging.

**trimmer punch.** The upper portion of the trimmer that contacts the forging and pushes it through the trimmer blades; the lower end of the trimmer punch is generally shaped to fit the surface of the forging against which it pushes.

**trimmers.** The combination of trimmer punch, trimmer blades, and perhaps, trimmer shoe used to remove flash from a forging.

**trimming.** The mechanical shearing of flash or excess material from a forging with a trimmer in a trim press; can be done hot or cold.

**trimming die.** See *cut-off die*.

**trimming press.** A power press suitable for trimming flash from forgings.

**triple-action hydraulic press.** A double-action press with a third independent movable slide built into the bed. A *cushion* is not considered a third action, but a third action may be construed to also act as a cushion.

**triple-action press.** A mechanical or hydraulic press having three slides with three motions properly synchronized for triple-action drawing, redrawing, and forming. Usually, two slides—the blankholder slide and the plunger—are located above, and a lower slide is located within the bed of the press. See also *hydraulic press*, *mechanical press*, and *slide*.

**triple junction/triple point.** Point at which three grains meet in a polycrystalline aggregate. Also, region in which high stress concentrations may develop during hot working or elevated-temperature service, thus nucleating wedge cracking.

**true strain.** A measure of strain in one direction that is obtained by integrating differential material strains to obtain  $\epsilon = \ln(l/l_0)$ , where  $l$  is the final length, and  $l_0$  is the original length in the direction of interest.

**true stress.** A measure of stress in one direction that is obtained by dividing the normal load

carried by a cross section by the current area corresponding to that load.

**tryout.** Preparatory run to check or test equipment, lubricant, stock, tools, or methods prior to a production run. Production tryout is run with tools previously approved; new die tryout is run with new tools not previously approved.

**tube stock.** A semifinished tube suitable for subsequent reduction and finishing.

**twinning.** Also called deformation or mechanical twinning, it is a deformation mechanism, similar to dislocation slip, in which small (often plate- or lens-shaped) regions of a crystal or grain reorient crystallographically to adopt a twin relationship to the parent crystal. It is particularly common in noncubic metals (e.g., alpha-titanium and tetragonal tin) and in many body-centered cubic metals deformed at high rates and/or low temperatures. Twinning is often accompanied by an audible crackling sound, from which “crying tin” gets its name.

**twist boundary.** Grain boundary for which the crystal lattices of the grains on either side of the boundary are related by a rotation about an axis that lies perpendicular to the plane of the boundary.

**two-hand control device.** A two-hand trip that further requires concurrent pressure from both hands of the operator during a substantial part of the die-closing portion of a press stroke.

**two-hand trip.** A means of clutch actuation requiring the concurrent use of both hands of an operator to trip a press. Requirements for a two-hand trip are as follows: (1) The individual operator's hand controls must be protected against unintentional operation. (2) The individual operator's hand controls must be arranged, by design and construction or by separation, or both, to require the use of both hands to trip the press. (3) A control arrangement must be used that requires concurrent operation of the individual operator's hand controls.

**two-high mill.** A type of rolling mill in which only two rolls, the working rolls, are contained in a single housing. Compare with *four-high mill* and *cluster mill*.

**TZM.** A high-creep-strength titanium, zirconium, and molybdenum alloy used to make dies for the isothermal forging process.

## U

**U-bend die.** A die, commonly used in pressbrake forming, that is machined horizontally with a square or rectangular cross-sectional opening that provides two edges over which metal is drawn into a channel shape.

**ultimate strength.** The maximum stress (tensile, compressive, or shear) a material can sustain without fracture; determined by dividing maximum load by the original cross-sectional

area of the specimen. Also known as nominal strength or maximum strength.

**ultrasonic inspection.** The use of high-frequency acoustical signals for the purpose of nondestructively locating flaws within raw material or finished parts.

**unbending.** The straightening of a previously curved section of sheet or beam.

**underdrive.** A press having the drive mechanism, including motor, flywheel, gears, shafts, and clutch, located in or below the bed.

**underfill.** A portion of a forging that has insufficient metal to give it the true shape of the impression.

**uniform elongation ( $\epsilon_u$ ).** The elongation that occurs at maximum load and immediately preceding the onset of necking in a tensile test.

**upset.** The localized increase in cross-sectional area of a workpiece or weldment resulting from the application of pressure during mechanical fabrication or welding.

**upset forging.** A forging obtained by *upset* of a suitable length of bar, billet, or bloom.

**upsetter.** A horizontal mechanical press used to make parts from bar stock or tubing by *upset forging*, piercing, bending, or otherwise forming in dies. Also known as a header.

**upsetting.** The working of metal so that the cross-sectional area of a portion or all of the stock is increased. See also *heading*.

## V

**vacuum forming.** Sheet-forming process most commonly used for titanium in which a blank is placed into a chamber that has a heated die, and a vacuum is applied to creep form the part onto the die. The part is usually covered with an insulating material, and the bag is outside this material.

**V-bend die.** A die commonly used in press-brake forming, usually machined with a triangular cross-sectional opening to provide two edges as fulcrums for accomplishing *three-point bending*.

**vent.** A small hole in a punch or die for admitting air to avoid suction holding or for relieving pockets of trapped air that would prevent die closure or action.

**vent mark.** A small protrusion resulting from the entrance of metal into die vent holes.

**viscosity.** Bulk property of a fluid or semifluid that causes it to resist flow.

**visioplasticity.** A physical-modeling technique in which an inexpensive, easy-to-deform material (e.g., clay, wax, lead) is gridded and deformed in subscale tooling to establish the effects of die design, lubrication, and so forth on metal flow and defect formation by way of postdeformation examination of grid distortions. See also *physical modeling*.

**von Mises strain.** See *effective strain*.

**von Mises stress.** See *effective stress*.

## W

**warm working.** Deformation at elevated temperatures below the recrystallization temperature. The flow stress and rate of strain hardening are reduced with increasing temperature; therefore, lower forces are required than in cold working. See also *cold working* and *hot working*.

**wear plates.** Replaceable elements used to face wearing surfaces on a hydraulic press.

**wear resistance.** Resistance of a sheet metal to surface abrasion. See also *erosion resistance*.

**web.** A relatively flat, thin portion of a forging that effects an interconnection between ribs and bosses; a panel or wall that is generally parallel to the forging plane. See also *rib*.

**wedge compression test.** A simple workability test in which a wedge-shaped specimen is compressed to a certain thickness. This gives a gradient specimen in which material has been subjected to a range of plastic strains.

**Widmanstätten structure.** Characteristic structure produced when preferred planes and directions in the parent phase are favored for growth of a second phase, resulting in the precipitated second phase appearing as plates, needles, or rods within a matrix.

**wiper forming (wiping).** Method of curving sheet-metal sections or tubing over a form block or die in which this form block is rotated relative to a wiper block or slide block.

**wire.** A thin, flexible, continuous length of metal, usually of circular cross section and usually produced by drawing through a die.

**wire drawing.** Reducing the cross section of wire by pulling it through a die.

**wire drawing test.** A test in which a cylindrical draw die is used to reduce the diameter of wire. The drawing force is measured and reflects lubricant effectiveness.

**wire rod.** Hot rolled coiled stock that is to be cold drawn into wire.

**workability.** See also *formability*, which is a term more often applied to sheet materials. The ease with which a material can be shaped through plastic deformation in bulk forming processes. It involves both the measurement of the resistance to deformation (the flow properties) and the extent of possible plastic deformation before fracture occurs (ductility).

**work hardening.** See *strain hardening*.

**work-hardening exponent.** See *strain-hardening exponent*.

**working stroke.** That portion of the press downstroke where force is being applied to shape sheet metal or retract pressure plates.

**workpiece.** General term for the work material in a metal-forming operation.

**wrap forming.** See *stretch forming*.

**wrinkling.** A wavy condition obtained in deep drawing of sheet metal in the area of the metal between the edge of the flange and the draw

radius. Wrinkling may also occur in other forming operations when unbalanced compressive forces are set up.

**wrought material.** Material that is processed by plastic deformation, typically to produce a recrystallized microstructure. Cast and wrought materials are produced by ingot casting and deformation processes to produce final mill products.

## Y

**yield.** The transition from elastic deformation, which is recoverable, and inelastic deformation, which is not.

**yield point.** The first stress in a particular material, usually less than the maximum attainable stress, at which an increase in strain occurs without an increase in stress. This is called the upper yield point. Also, a second, lower stress where the stress stops falling with increasing strain is known as the lower yield point. Only certain metals—those that exhibit a localized, heterogeneous type of transition from elastic to plastic deformation—produce a yield point.

**yield point elongation.** The extension associated with discontinuous yielding that occurs at approximately constant load following the onset of plastic flow. It is associated with the propagation of Lüder's lines or bands.

**yield ratio.** The ratio of the yield strength to the *tensile strength*. It is the inverse of the tensile ratio.

**yield strain.** The strain in a tension test corresponding to the yield stress. In principle, it may be obtained by dividing the yield stress by Young's modulus.

**yield strength.** The stress at which a material exhibits a specified deviation from proportionality of stress and strain. An offset of 0.2% is used for many metals. Compare with *tensile strength*.

**yield stress.** A stress at which a material exhibits the first measurable permanent plastic deformation.

**Young's modulus.** A measure of the rigidity of a metal. It is the ratio of stress, within the proportional limit, to corresponding strain. Young's modulus specifically is the modulus obtained in tension or compression.

## Z

**Zener-Hollomon parameter (Z).** See *temperature-compensated strain rate*.

**zero-extension fiber.** The location through the cross section of a bent beam or sheet where the material elements neither elongate nor compress. The location may be a theoretical one outside of the sheet or beam.
